LWRs and can be recycled, so that the resulting natural resource utilization can be nearly two orders of magnitude higher than in contemporary LWR. The second potential drawback is that shielding of fast neutrons can require larger shield volumes and thicknesses than when shielding for thermal neutrons (Waltar et al. 2012). This is primarily a consideration for the smallest units considered (micro-reactors and small-modular reactors (SMR)) where compactness of the overall system can be of the highest importance. For SFR systems typically considered for base-load electricity generation, shielding, while an important aspect, is not typically a major limitation.

Reactor physics aspects of fast versus thermal neutrons

Some basic reactor physics discussion is necessary to appreciate the differences between thermal and fast neutron systems (DOE, 1993a,b; Waltar et al., 2012). Neutron having an energy above 0.1 MeV (100,000 eV) are generally considered fast neutrons, and those with an energy below 0.625 eV are considered thermal neutrons. In a simplified way, neutrons arising from a fission event have an energy distribution peaking around 0.5–1.0 MeV (Klay, 2021). When a moderating material is present, the energy of those neutrons is quickly knocked down from the fast energy range to the thermal energy range, which results in spectra observed in thermal reactors with the usual two-hump shape as shown in Fig. 6. When no moderator is present, neutron scattering is still occurring but neutrons lose significant less energy and are typically absorbed or leak out of the core before reaching thermal energies.

Granted that every isotope has different cross-sections, some general trends can be observed when looking at cross-section distribution for commonly used isotopes: cross-section values at fast energies tend to be significantly smaller than at thermal energies but the fission-to-capture probability is higher and the number of neutrons emitted per fission is significantly larger at high energies (Klay, 2021). From those basic observation, we can globally understand some of the key differences between thermal and fast reactor systems, as summarized in Fig. 7. This helps understand why fast reactors require a higher minimum fuel enrichment level, compared to LWRs, to be critical, why they are able to serve multiple roles such as being capable of incinerating (fissioning) minor actinides or breed actinides, why a larger variety of structural materials can be used, and why extremely high fuel utilization can be achieved.

A potential miss-conception is that SFRs require more initial fissile material than LWRs. However, because of their superior neutron economy, SFRs can readily be designed to be breeders; that is to make at least as much fissile fuel as they consume, so no enriched uranium is required after the initial fuel loading; depleted uranium or natural uranium can be used for the SFR makeup fuel. Additionally, SFRs can be designed to have a fissile material requirement, per unit energy, lower than contemporary LWRs.

Major technology description

While at a high level, the key difference between SFRs and LWRs is the absence of a moderator and water being substituted with sodium as coolant, there are a lot more differences when diving into the technology details. Some insight is provided here on the technology details pertaining to the nuclear island, some of the reactor systems, and the safety impacts. It must be noted that only dedicated books (or other supports) will be able to provide a comprehensive description and discussion of those details. Like for all reactor technologies, there are many systems present in SFRs that cannot be highlighted in an encyclopedia chapter. These systems are serving a multitude of purposes, from purification systems to sodium cleanup systems. They aim at increasing the safety, reliability, and maintainability of the power plant.

Core features/options

SFR cores can be designed in many ways due to the flexibility enabled by fast neutrons. A large number of materials, typically ruled out from use in thermal reactors because of their negative impact on the reactor performance, are possible choices for SFRs (Walters et al., 2011). With sodium as the coolant, SFRs are typically expected to operate with coolant temperatures in the range of 300–600 °C

(IAEA, 2007). At those temperatures, special consideration needs to be given to structural material performance and compatibility. Those considerations are unique for each design and as such no additional discussion is provided on this topic in this article.

Almost any fuel type can be used in a SFR (Walters et al., 2011). This goes from the well-known oxide fuels to the less common inert matrix fuels, encompassing metal, carbide, nitride and even coated particle fuels. SFR operating experience primarily pertains to oxide fuels (UO_2 and UPuO_2) as this fuel form has been used the most around the world for nuclear reactors of all types, but other fuel forms have also been used. In particular, metal fuels (Hofman et al., 1997) have been extensively irradiated in SFRs such as the experimental EBR-II because of their enhanced safety performance benefits (FRWG, 2018; Sofu, 2015). While any fuel form, beside those bearing moderating materials (e.g., TRISO), can be used in SFRs, not all those fuel forms are qualified or even mature enough to undergo a licensing review. Characteristics of importance for SFR fuels are fuel forms allowing to achieve high heavy metal loading, good thermal performance and good irradiation stability.

Materials used for structural integrity within the core, including fuel cladding, have typically been steel-based alloys. These materials are preferred due to their compatibility with sodium, relatively low impact on the neutron economy of a SFR, and general availability. Furthermore, they are easy to work with, are relatively inexpensive, and benefit from a tremendous knowledge basis.

Another material of importance in a SFR core is the absorber material, typically used as part of the control elements and potentially in shield components. Noteworthy is that EBR-II did not use an absorber in its control elements, but rather relied on the opposite approach, consisting in withdrawing specific fuel elements when needing to reduce the core reactivity. Although the absorption cross-section of boron is significantly smaller in fast-spectrum systems than in thermal-spectrum systems, it still remains one of the most effective absorber for fast neutrons, especially the ^{10}B isotope. While there are other materials with larger absorption cross-sections in the fast energy range, the commercial availability of B_4C and experience as a control material in thermal reactors makes it the preferred absorber material in SFRs (IAEA, 1996a).

Some typical SFR core layouts are shown in Figs. 8 and 9. It is typical for SFRs to use an hexagonal lattice of fuel assemblies, rather than the traditional square lattice used in LWRs, as it leads to more compact cores featuring high fuel volume fraction. This is enabled by the thermal hydraulics properties of sodium, making it possible to achieve very high-power densities: the footprint of a SFR core is typically smaller than that of LWRs for the same power level. Fuel assembly designs are different across the various SFRs, but are typically made of a duct providing both structural support and a coolant flow path to each assembly. Fuel assemblies, schematically shown in Fig. 10 would contain a number of fuel pins assembled in a triangular array, with space between pins maintained either by spacers or by a wire wrapped around the pin. The fuel pins are made of a cladding holding together the fuel, which can be in the form of pellets or slugs depending on the fuel used.

Other assemblies in a SFR core include control assemblies, reflector assemblies and potentially shield assemblies. Reflector and shield assemblies can be made of reflector/shield rods or other geometries such as block-type components when desirable. The control assemblies, shown in Fig. 11, are typically double-duct systems. The outer duct, being the same as that of other assemblies, fixed in position within the core during normal operations. The inner duct can be moved up and down as needed by the reactor

control system and control rod driveline mechanism. This inner duct contains an array of absorber rods organized in a triangular lattice. Those rods are made of a cladding containing the absorber material, typically B_4C .

The general assembly arrangement depends on the particular mission tackled. SFRs can be configured as burner, breeders, or break-even reactors (Hoffman et al., 2008). Burner reactors are reactors which are net consumers of fissile material, are able to transmute actinides or consume minor actinides. Breeder reactors are reactors which allow generating more fissile material than they are consuming, or turning a given fissile isotope into a different fissile one (e.g., fueling with fuel bearing ^{235}U to generate ^{233}U in thorium fuel). Break-even reactors, are reactors which are fissile-fuel self-sustaining, without generating more fissile material than they are consuming. These various SFR missions are discussed in more details further down in this article. The characteristics of the assemblies, their arrangement, the number of control assemblies, and the dimensions of the core can vary greatly depending on the targeted SFR mission.

With fast neutrons having a large mean free path, shielding is very important. Two of the main concerns addressed by shielding, in addition to biological shielding, are activation of the primary or secondary sodium and radiation damage of the load-bearing in-vessel components. Sodium activation can lead to high dose rate arising from the sodium circulating outside of the reactor vessel, which would lead to needing excessive shielding around the sodium circuit. Radiation damage, often calculated in displacement per atom (dpa), can lead to deterioration of the mechanical properties of structural materials in the vessel, such as embrittlement. While radiation damage occurs with any reactor technology, this is of a higher concern in fast reactors as neutron flux levels tend to be higher and neutrons are more energetic, leading to higher dpa rate (NEA, 2015). This can typically be addressed through proper shielding design and maintenance planning.

There are two main approaches used for neutron shielding in SFRs. One consists of using an absorber material, such as B_4C , in large enough amounts to achieve the desired effect. The other one consists of using a moderating material, such as graphite, paired with a material absorbing thermal neutrons, such as steel. The tradeoffs of both approaches are complex and depend on the specific reactor design. The first approach could lead to a more compact shielding solution, while the second relies on somewhat simpler materials which may have a cost advantage.

The sodium flows from the bottom to the top of the core, which allows taking full advantage of the natural circulation capabilities of sodium during transient scenarios. The flow rate in each assembly is determined by the hydraulic resistance of the assembly, as typically there is no active mechanism to allocate flow rate to the various assemblies, and all assemblies are hydraulically connected together at their extremities. The hydraulic resistance in different radial parts of the core can be adjusted to approximately match the radial power distribution so that the sodium temperature rise across different fuel assemblies will be as close as practical to the core average. As the coolant exits at the top of the assemblies, it is mixed together and continues through the rest of the primary system towards the heat exchanger.

Nuclear Island configurations

Looking at a SFR from the outside, there are no obvious differences with any other nuclear power plant. Once heat is extracted from the sodium coolant, the technologies used in the rest of the energy transfer system are not unique to SFRs, even though their specifications are tailored to the specific conditions expected. The operating temperatures of SFR are such that thermal efficiencies of around 40% are common when heat is converted to electricity. The heat from the coolant (or that transferred to additional loops) could enable some process-heat applications, but cannot achieve temperatures as high as those achievable with reactor technologies such as high-temperature gas-cooled reactors (HTGR) and molten-salt reactors (MSR) (Stanculescu, 2021). When a SFR is used as a research, test, experimental or demonstration reactor, it is possible that neither an energy conversion system, nor a process heat plant is associated with the reactor, and that the heat is simply rejected into the atmosphere.

Inside the containment building (IAEA, 1996b; Grandy et al., 2016), there are two different plant configurations commonly used for SFRs (Waltar et al., 2012): the loop-type and pool-type configurations illustrated in Fig. 12.

The loop-type configuration is conceptually similar to the general configuration of LWRs. The core components are tightly contained in a fitted vessel and the primary coolant system exits the vessel to reach the intermediate heat exchanger (IHX). This layout still requires a secondary coolant loop as sodium in the primary system is highly activated and in the very unlikely event of a leak from the primary to the secondary coolant system, reaction between radioactive sodium and water will be prevented.

The pool-type configuration consists of a large vessel containing the entire primary coolant system, including the pump(s), IHX(s) and other components. It is labeled as a “pool” as all the components are submerged in sodium. In that configuration, the secondary coolant loop passes through the vessel boundary.

The major benefits and drawbacks of both configurations are summarized in Table 2. Maintenance of the systems is made easier in the loop configuration as fewer components are submerged in the primary sodium, making accessing them and replacing them a somewhat simpler endeavor. The sodium inventory in the loop configuration is significantly less than that of the pool configuration which results in a smaller overall mass of the primary system. Shielding of the secondary sodium, that in the secondary coolant loop, is made easier in a loop configuration as the IHX can be located as far as needed from the reactor core and shielding to that effect can be placed outside of the vessel, in-between the vessel and the secondary coolant system.

The pool configurations are less compact but also offer more space within the vessel. This provides more flexibility to incorporate the various components needed in the system. It can also simplify fuel handling operations, and even include used fuel storage locations within the vessel. The main benefit of the pool configurations has to do with the safety aspects. Pool-type configurations are virtually immune to loss of coolant from the primary system, offer a significant heat sink which leads to highly favorable transients and make passive heat removal systems simpler to integrate.

There is no clear preference across the SFR community regarding the pool-type versus loop-type configurations (IAEA, 2007). While certain countries seem to favor one over the other, this is possibly due to the experience accumulated with the configuration selected for their first SFR, making it preferable to retain that configuration for subsequent SFRs. Understanding the application intended for a SFR design can drive the preference towards one configuration or the other. For instance, a SFR to be operated as a test reactor might favor a pool configuration due to the enhanced inherently safety behavior and the extra space available to handle experiments.

Reactivity control and shutdown systems

While some of the early SFRs relied on a single reactivity control system, the current standard is to include two independent reactivity control systems (U.S. NRC, 2018). The first one, commonly referred to as the reactivity control system, is used to control the core reactivity level and therefore its power level over the entire range of operational conditions. It can also be used to single-handedly bring the reactor from any anticipated operational condition into a safe sub-critical state. The second reactivity control system, commonly referred to as the safety or shutdown system, is not used to control the power of the reactor and its sole role is to provide an independent means to quickly bring the reactor from any anticipated operational condition into a safe sub-critical state.

Both systems are usually made of several assemblies containing an array of absorber pins, which are able to slide into fixed assembly duct locations. The absorber material of choice is B_4C due to its availability and extensive knowledge basis. However, other absorber materials are sometimes considered such as Hf_xH as they can provide benefits such as a lower rate of reduction of the reactivity worth with absorber burnup.

Due to the low burnup reactivity swing occurring in SFRs over the course of a cycle, burnable absorbers typically used in LWRs are unnecessary, leading to a simplification of the reactivity control strategy. The initial, uncontrolled, excess reactivity in a SFR is 5–10 times lower than the typical value in LWRs.

Reactor and guard vessels

The reactor internals, which at a minimum include the core components, control systems and instrumentation, are contained within the reactor vessel. The reactor vessel is a solid shell, typically made of steel, which role is to contain the primary sodium, the various internals, and constitutes one of the protection barriers against the release of radioactive products. The thickness of the reactor vessel depends on the size of the reactor, volume of sodium, weight of the internals it supports, and radiation shielding needs. Typical thicknesses are less than 5 cm. It can be hung from the top, or directly supported at the bottom. These two approaches lead to slightly different seismic response behavior. The reactor cover head is a thick plate of steel closing the reactor vessel and allowing

Liquid Metal cooled Fast Breeder Reactors (LMFBR)

Fig. 12 Schematic comparison of pool-type versus loop-type layouts for SFRs. Source: Wikipedia.

Table 2 Major differences between loop-type and pool-type SFR configurations.

Characteristics	Loop-type	Pool-type
Primary coolant	Exit vessel	Within vessel
Primary vessel	Compact, less in-vessel space	Large
Primary system components	Outside vessel	Within vessel
Safety aspects	Reduced sodium inventory	Minimized coolant pipe break impact, large heat sink
Leak prevention	Guard vessel; double-walled coolant pipes	Guard vessel
Maintenance	Ease of access and to isolate the primary loop	Mostly under sodium

necessary penetrations for the control systems, instrumentation, and such. Specific reactor vessel layout and arrangement depends on the SFR design and its overall configuration.

The reactor vessel is usually surrounded by a guard vessel which plays the role of a failsafe vessel as it envelopes the reactor vessel. The gap between the two vessels does not contain sodium and typically is filled with an inert gas or with air. This gap is large enough to allow inspection through remote means, but small enough to ensure that in case of failure of the reactor vessel, the core will remain submerged under sodium and decay heat removal systems remain operational.

Fuel handling and storage/refueling system

The primary sodium activity builds up during normal operations due to activation of ^{23}Na into ^{24}Na through neutron capture. With ^{24}Na half-life being about 15 h, it would take several days or weeks for the activity levels to reach a low enough value to allow direct access for refueling. In addition, with the sodium refueling temperature typically being in the 200 °C range, refueling operations in SFRs are routinely performed with the cover head in place. There are several ways in which refueling can occur in a SFR, but all have some similarity. For instance, assemblies being removed from the core are handled under sodium or inert gas atmosphere. With sodium being opaque, careful planning of assembly handling is necessary and specific features are built into the designs to prevent miss-loading of assemblies. Additionally, under-sodium viewing techniques have been developed but do not replace careful planning (Griffin et al., 2009).

As part of the process of removing used assemblies from a SFR core, discharged assemblies are moved from the sodium environment to a sodium washing station. There, residual sodium still present in the assemblies is being removed under inert atmosphere before used assemblies can be stored. Before being discharged from the sodium environment, fuel assemblies are kept within the reactor vessel until their decay heat is compatible with the fuel transfer technology and protocol in place for that particular reactor. It can take several months for the decay heat to drop to the desired levels, interim storage or in-vessel storage space is typically available away from the active core region.

Heat transport systems

The primary coolant system removes heat from the nuclear core, and transfers it to the secondary coolant system through the IHX. As sodium is a light liquid metal at typical operating conditions, it can be circulated through the primary system using either mechanical pumps or electromagnetic pumps. The tradeoffs between these two pump technologies do not result in either technology being significantly more attractive than the other. While natural circulation can be relied upon to remove heat from the core, especially in some of the postulated unprotected transient scenarios, it is insufficient to establish flow rates consistent with the high power density achieved under normal operating conditions in most SFRs.

Intermediary heat exchangers come in various shapes and forms, but in all cases they transfer heat from the primary coolant system to the secondary coolant system. Sodium is used as the cooling material in the secondary system in order to avoid any risk of the activated primary sodium to come in contact with air or water. This would lead to burning, pressurization of the primary coolant system and potential dispersion of radioactive isotopes outside of the primary coolant system. Similar to the primary coolant system, the sodium contained in the secondary system is circulated by mechanical or electromagnetic pumps.

Heat is removed from the secondary coolant system through a steam generator, for electricity generation, or directly dumped in the environment, typically into the air, in case of research or test reactors. This part of the plant does not differ in any major way from that encountered with the other reactor technologies. For instance, either conventional steam cycles or supercritical CO_2 Brayton cycles can be used for the energy conversion system. As operating temperatures are higher in SFRs than in LWRs, the thermal efficiency of SFRs is typically around 40% versus about 32% of LWRs.

Decay heat removal systems

After a reactor is shutdown, decay heat is still generated over time and initially amounts to several percent of the nominal reactor power. Proper removal of the decay heat is key in order to ensure fuel integrity and has been the source of most of the adverse consequences of the various nuclear accidents around the world. In SFRs, during normal shutdown the decay heat is simply removed

through the balance-of-plant, dumping the heat in a heat-sink. During hypothetical accident scenarios where the balance-of-plant is unavailable, the decay heat is removed by safety-grade heat removal systems (passive or not) which become enabled as the reactor temperature rises. More details about those systems are provided in the safety section of this article.

Containment

The containment building is the last barrier of defense-in-depth (Grabaskas et al., 2015) against the uncontrolled release of radioactivity. During hypothetical accident scenarios a SFR containment would experience a set of conditions different from that expected from LWRs or other types of reactors. Being a low pressure system, pressurization does not play a major role for an SFR containment building, and the same goes for highly energetic Maximum Hypothetical Accidents (MHA). Experiments, analyses and experience have shown those situations to be excessively unlikely for SFRs. Rather, the design basis for the containment building shall consider large sodium fires as the bounding set of conditions. Protection against large sodium fire is typically achieved through appropriate design of the guard vessel for pool-type SFRs, and through double-walled piping for loop-type SFRs.

Instrumentation and Controls

Various instrumentation is used to monitor a SFR, similarly to other reactor technologies. Characteristics of interest include the neutron flux, various temperatures, coolant flows and pressure. These are needed to inform the reactor control system and the plant protection system, as well as the operators in order to ensure the safe operation of the plant. The conditions experienced in a SFR and the properties of sodium being unique to that reactor technology, this leads to a different selection of the proper monitoring instruments.

For instance, flux monitoring can be achieved with neutron detectors such as fission chambers located outside of the reactor vessel in order to protect them from high temperatures and neutron fluxes, which could reduce their lifetime or reliability. Positioning of these detectors several meters away from the core and still obtaining accurate flux monitoring is made possible by the high flux and large neutron mean free path which are unique features of fast reactors.

Coolant temperature and flow are measured at different points in the primary and secondary coolant loops and are used to determine the core thermal power. Propagation of the coolant conditions through the coolant loop and response time of the instrumentation selected can insert some small delay in obtaining the accurate core condition, which needs to be consistent with the desired response time of the reactor control system.

Safety considerations

Passive safety

One of the main value proposition of the advanced reactor technologies is to offer improved safety performance and behavior (Ruggieri et al., 2017), compared to the previous generations of reactors. While existing reactors have been shown to be extremely safe, advanced reactors and including SFRs, offer the opportunity to achieve passive safety—sometimes referred to as inherent safety (IAEA, 2020; ANL, 2002; Till and Chang, 2011). The main benefit is that the reliance on safety-grade safety systems needing to be activated to ensure the safety and preservation of the plant is significantly reduced. This can help reduce the complexity of the instrumentation and control systems, and therefore of the associated costs and risks. While passive safety can theoretically be achieved with any of the advanced reactor technologies, the design space enabling it is quite limited for some of those technologies. For SFRs, while passive safety is not guaranteed for every design configuration, it is a reactor technology for which it is readily achievable.

Before jumping into the passive safety features of SFRs and how it is achieved, a general sense for the meaning behind “passive safety” is required. A reactor can be considered safe if during normal operation and any possible anticipated operational occurrence it is able to remain in a safe state, preventing radioactivity release, exposure, or failure of critical components (e.g., vessel rupture, core melting, etc.). A safe reactor is not immune to unexpected events happening or to random equipment failure; but it guarantees that in such scenarios the public, workers and capital asset will not be jeopardized. A passively safe reactor does not guarantee more than that, but it is able to achieve those safety objectives through relying uniquely on passive systems or behaviors. It is also important to note that because a reactor is passively safe, it does not mean it does not contain any active safety systems, or does not rely on active systems to maintain control of the reactor. Passive safety can be seen as the guarantee that even when everything goes unexpectedly wrong, the reactor will remain in a safe state. Autonomous reactor operation, while potentially synergistic with passive safety, is a different matter, not discussed here.

Excess reactivity and self-compensation

In a simplified way, two key requirements of reactor safety are the ability to prevent excessive increase of the core reactivity and to prevent excessive temperatures to be reached. Controlling excess reactivity is typically achieved through relying on activation of the control (or safety) rods/blades when the reactor control system detects abnormal conditions. A passively safe reactor is able to mitigate reactivity excursions even without control rods being activated. For SFRs this is achieved through favorable reactivity feedback coefficients, which are combining together to maintain the reactor in a controllable state. Although there are multiple postulated

accident scenarios to consider and analyze when performing a safety assessment, all with different assumed successions of events, we can provide a general description of the general trends. When reactivity of the core unwillingly increases (e.g., accidental removal of a control element, core compaction, etc.) the power generated by the core will increase. In turn, this inevitably leads to an increase of the fuel, cladding and coolant temperatures. The increase in coolant temperature will also lead to an increase of the core support structure temperature and therefore to its thermal expansion. All of these temperature changes lead to a number of feedback mechanisms: Doppler feedback from the fuel, fuel density feedback, cladding density feedback, coolant density feedback, and core axial and radial expansion feedbacks. Not all feedbacks build up at the same moment, and the particular reactor configuration quantitatively affects the actual trends. However, it is well understood that one could not expect significant increase of the coolant temperature without an increase of the fuel and cladding temperature, since the heat is mostly arising from the fuel itself. In SFRs, the combination of these feedback mechanisms commonly leads to a compensation of the accidental reactivity insertion. That reactivity compensation is achieved at temperatures above those observed at nominal conditions. Depending on the particular accident scenario assumed, when relying only on passive mechanisms (i.e., assuming control/safety rods are not responding), passively safe SFRs can either remain critical at higher operating temperatures or shutdown on their own. Those trends, described here in a simplified fashion, have been demonstrated in most past and present SFRs and the ability of SFRs to passively handle all kind of transients is unequivocal. This includes even the most severe beyond design basis accident (BDBA) scenarios postulated for SFRs.

Decay heat management

The second aspect mentioned, pertaining to a safe reactor, is its ability to prevent temperatures to exceed design limits, which could lead to fuel melting, coolant boiling, cladding failure or other highly undesirable and potentially impactful events. While preventing excessive increase of the core reactivity is essential, it does not guarantee that temperatures during transient scenarios would remain acceptable. Peak temperatures reached during postulated transients are highly dependent on the SFR design characteristics. Characteristics that affects those temperatures are the heat transfer characteristics of the system and the power to flow ratio during transients. A key challenge for passive safety with any reactor technology is the management of decay (residual) heat for transient scenarios postulating a loss of forced cooling or of the ultimate heat sink. In those situations decay heat cannot be removed through the intended pathways and if no appropriate design features exist it will lead to ever increasing temperatures. There exist several systems allowing passively removing the residual heat (Ashurko, 1996; ORNL, 1985) during the most stringent transient scenarios, such as Direct Reactor Auxiliary Cooling System (DRACS), Primary Reactor Auxiliary Cooling System (PRACS), Intermediate Reactor Auxiliary Cooling System (IRACS), Reactor Vessel Auxiliary Cooling System (RVACS), or Steam Generator Auxiliary Cooling System (SGACS). All these rely on the ability of SFRs to establish natural circulation through the core, as the sodium temperature differential allows overcoming the primary system hydraulic resistance. For the extremely low flow rates required to remove the residual heat, most of the hydraulic resistance is potential energy. Usually only one of the passive heat removal systems mentioned is implemented in a given design, but all consist in creating an alternate pathway for small amounts of heat to be passively removed from the core. They are sized based on the anticipated decay heat to be handle, and to only become effective when the system temperature rises, as to avoid heat losses during normal operations. Since these systems rely on the primary system to not be drained from all its coolant, SFRs have design features preventing large loss of coolant situations (guard vessel and double-wall pipes).

Many additional safety features exist in the various SFRs, some shared among designs, some design-specific. Overall, the physics of SFRs and the thermal-hydraulics properties of sodium lead to extremely favorable safety behaviors. In particular, SFRs can easily survive BDBA without adverse consequences to the public, workers or even capital asset. While higher-than-normal temperatures can be reached during some BDBA, these retain margins from temperatures that would lead to irreversible plant damage.

SFR missions

With the flexibility exhibited by SFRs (due, to a large extent, to their intrinsic reactor physics characteristics) with respect to the range of viable design options (fuel, materials, layouts, etc.), SFRs are well suited to address a number of potential missions. SFR can be designed as power reactors all the way to radio-isotope producers, including all kinds of material transmutation, and irradiation testing capabilities (Waltar et al., 2012).

Power reactor

When intended as power reactors, SFRs can allow to significantly increase resource utilization as well as significantly reduce the amount of waste produced. Because they tend to require higher enrichment level than thermal reactors, the absolute Separative Work Unit (SWU) per mass of fuel is higher. However, as a significantly higher burnup and a larger fraction of the mined materials can be consumed in a SFRs, the importance metrics is the amount of energy produced per mass of fuel, per SWU, or per mass of mined resource.

In thermal spectrum reactors, accumulation of fission products leads to a significant reactivity penalty which is one of the main limitation to the burnup the fuel can achieve. In fast spectrum reactors accumulation of fission products does not bear such a significant reactivity penalty as the cross-sections of all fission products are orders magnitude lower than in a thermal spectrum reactors. As such, the fuel burnup of SFRs is rarely limited by fission product accumulation, allowing to reach very high burnups. Instead, the

burnup achievable in SFRs tends to be limited by the radiation damage limits imposed on the fuel or cladding materials. Burnup levels of about 20% FIMA (Fission per Initial Metal Atom) have been achieved in SFRs without needing fuel reprocessing or any fission product removal.

While consumption of the fissile material can theoretically limit the fuel burnup, SFRs can be configured as burner, break-even or breeder reactors. For break-even and breeder configurations, depletion of the fissile material is not typically a limitation for the fuel burnup. Instead, the burnup in SFRs is usually limited by either degradation of the fuel performance or of its cladding. With increasing burnup, the fuel composition is changing and its properties as well. Some of the fuel performance characteristics that may become limiting are the fuel swelling, thermal conductivity, mechanical integrity, fission gas release, and constituents relocation (Pahl et al., 1992; Hofman et al., 1997; Jensen and Woolstenhulme, 2021). From the cladding perspective, cladding wastage and degradation of its mechanical properties due to neutron induced radiation damage leads to a limitation of the burnup that the fuel can reach. In those cases where the burnup is not limited by reactivity considerations, the fuel could theoretically be reprocessed or reconditioned and directly reused in the reactor.

The resource utilization in a SFR relative to a LWR can be roughly estimated using approximate values. Assuming LWRs using 4.2% LEU and achieving a fuel burnup of 50 GWd/t, their resource utilization is approximately 0.6%, meaning that not even 1% of the energy contained in the mined uranium is extracted. While assuming that the fuel burnup of SFRs is limited by the fuel or cladding performance under irradiation, burnup levels of 200 GWd/t have been regularly achieved. With SFRs requiring LEU containing around 15% ^{235}U , the amount of energy per unit mass of ^{235}U is only about 13% more than in a LWR. When reprocessing the fuel, SFRs can recycle the fuel indefinitely, using depleted uranium as the makeup fuel (no uranium enrichment is needed beyond the initial fuel loading). This allows SFRs to make use of the large amount of the depleted uranium accumulated during the fuel enrichment process. While in theory this could lead to fuel utilization of nearly 100%, losses occurring during reprocessing and fuel fabrication reduce the achievable fuel utilization to $\sim 90\%$ (Krepel and Losa, 2021). This estimate is highly dependent on the reprocessing and fabrication losses, the ability to recover those losses, and the particular processes used. Furthermore, losses for a given process are typically getting reduce as the process keeps getting refined.

While this thought exercise is focused on LEU for the initial fuel loading, SFRs can be fueled with fissile materials other than ^{235}U , such as excess plutonium from the military program or plutonium extracted from LWR used fuel.

Core configurations

The configuration of a SFR core can be set in different ways depending on the objective. Typically, the possible core configurations can be sorted into three categories: burner, breeder and break-even. Those are not three widely different approaches to core configurations, but rather should be seen as a continuous configuration morphing from burner to breeders, with the conversion ratio being the differentiator.

Burners

In a burner configuration (Hoffman et al., 2008) the core consumes more fissile material than it generates through neutron capture in fertile isotopes such as ^{238}U or ^{232}Th . The conversion ratio (CR) of burners is less than unity. This is the preferred configuration when one of the reactor missions is to transmute materials such as trans-uranium (TRU) actinides from used fuel. Burner SFRs are purposely designed to require large fissile and low fertile fuel loadings such as to minimize new fissile material generation and maximize TRU incineration rate. This is achieved through high parasitic neutron capture and leakage probability. The capture process is typically part of achieving the transmutation goals. Usually, burner configurations, illustrated in Fig. 10, feature a large reactivity swing during an operating cycle and therefore tend to require a larger number of control rods than other SFR configurations. By burning TRU from LWR used fuel the LWR resource utilization is effectively increasing.

Breeders

In a breeder configuration, illustrated in Fig. 9, the core generates more fissile material (usually primarily ^{239}Pu) through neutron capture in fertile isotopes (usually ^{238}U) than it consumes. It has a breeding ratio (BR) larger than unity (Till et al., 1980; Krepel and Losa, 2021) which depends on the fuel considered, as shown in Fig. 13. Alternately, a given fissile material can be turned by a breeder reactor into a different type of fissile material; for instance using LEU to breed ^{233}U in thorium fuel.

Breeder SFRs benefit from making the most of the neutron economy, as every neutron captured in the fertile material contributes to the end goal. Parasitic neutron capture and large neutron leakage probabilities are undesirable. However, when neutron leakage probability is excessively reduced it may adversely impact the favorable passive safety features of SFRs. When the sodium density is reduced (e.g., temperature increase), the spectrum tends to harden and reactivity increases. This is balanced by a fractional increase of the neutron leakage probability that reduces the core reactivity. As such, if the initial leakage probability is very small, the fractional increase in leakage probability during transients may not be sufficient to compensate the reactivity effect of spectrum hardening.

Breeder SFRs take advantage of fuel loading with low fissile fraction and large fertile fraction and are designed with high volumetric fuel fraction, leading to relatively compact cores with hard neutron spectrum. It is common for these to include radial and/or axial blankets at the periphery of the core to make the most of neutrons leaking out of the active core region, maximizing achievable breeding. However, breeding in blankets elements can raise some proliferation concerns that must be addressed carefully. As the

Fig. 13 Breeding ratio for various fuel types as a function of the fuel volume fraction in the SFR core (Till et al., 1980).

burnup reactivity swing in the breeder SFRs tends to be about zero or slightly positive, they usually require fewer control rods to achieve the desired shutdown and control performance.

Breeder SFRs are primarily intended for situations where there is a need to increase the fuel fissile inventory in order to support a growing fleet of nuclear reactors by using the extra fissile material bred for the initial fissile loading of new reactors (without the need for uranium enrichment). The high breeding gain that can be achieved with SFRs is attractive for all nuclear energy growth scenario envisioned by the different governmental agencies around the world, making SFRs a strategic technology in growing nuclear capacities without taking a toll on our natural resources.

Break-even

In a break-even configuration the core generates as much fissile material as is being consumed. It has a breeding ratio equal or slightly larger than unity. Their makeup fuel is a fertile material such as depleted or natural uranium. That is, break-even SFRs are self-sustainable from a fissile standpoint. In practice, the core might generate a little bit more fissile material than it consumes in order to make up for reprocessing/reconditioning and fabrication losses. Break-even SFRs are at the mid-point between burner and breeder SFRs, somewhat mitigating proliferations challenges of having a breeder SFR and the resource utilization limitations of the burner SFRs.

Break-even SFRs would be advantageous in a situation where the system electricity production capacity through SFRs has reached a stable point, with no need for increasing the fissile fuel inventory to start new reactors, and a desire to conserve natural resources.

Transmutation mission

SFRs have regularly been considered as a highly attractive option for High Level Waste (HLW) transmutation (IAEA, 1993). They can use minor actinides from spent fuel, some of which have half-lives of hundreds of thousands of years, and progressively fission those (Krepel and Losa, 2021; Boullis and Chabert, 2021). This results in a tremendously reduced amount of minor actinides, or even a near complete consumption if kept long enough in the reactor (Wigeland et al., 2015, 2021). Beyond transmuting minor actinides, SFRs can also serve to transmute used fuel from other reactors and in particular consume or denature plutonium found in those fuels. Some physics considerations are discussed here to provide a basic understanding of these transmutation capabilities.

From a transmutation perspective the key reactor physics characteristic of interest is the ratio between capture and fission for each actinide. Some representative values for these ratio are shown in Fig. 14 for actinides created by successive neutron capture in the uranium and transuranium isotopes. In essence, when a fission occurs in an actinide nucleus, it is consumed. However, when

Fig. 14 Representative fission to absorption ratio for selected actinides in SFRs and LWRs (PWR). (absorption = fission + capture).

a capture occurs that actinide nucleus is merely turned into another actinide. While this can be beneficial if the newly formed actinide has favorable properties (e.g., shorter half-life than its parent), this leads to accumulation of heavier actinides (Koch, 1986).

Based on the information of Fig. 14, we can understand what happens to actinides generated from capture in uranium in thermal-spectrum and fast-spectrum systems, and how the heavier actinides accumulate. For instance, when a neutron is absorbed in ^{238}U , it will result in a fission event about 10% of the time in a thermal reactor and about 18% of the time in a fast reactor. This means that, respectively, 90%/82% of the time the ^{238}U atom will not be destroyed, but rather transmuted into another actinide. While for the fissile isotopes ^{235}U , ^{239}Pu and ^{241}Pu as well as for the fertile isotope ^{238}U the difference between thermal and fast reactors is not game-changing, it is for other isotopes. Using ^{242}Pu for illustration, when a neutron gets absorbed in ^{242}Pu in a thermal reactor, it will get transmuted into another actinide about 98% of the time, not resulting into any noticeable reduction of the actinide inventory. In contrast, when a neutron gets absorbed in ^{242}Pu in a fast reactor, it will get transmuted into another actinide only about 48% of the time. The remaining 52% of the time ^{242}Pu will fission and contribute to reducing the actinide inventory.

The successive actinides build up is hence schematically shown in Fig. 15, starting from ^{238}U . In most reactors ^{238}U would not be present in isolation and other actinides would be initially present. The way to read this figure is “for one neutron absorbed in ^{238}U , we would get 0.90/0.82 atoms of ^{239}Pu in a thermal/fast spectrum system,” and so on. This does not account for the different neutron economy of thermal and fast reactors or the different initial actinide concentrations. Overall, LWRs are expected to accumulate over 20 times more minor actinides than SFRs. This can also be stated as SFRs being able to consume minor actinides at over 20 times the rates of what could be achieved in LWRs. This is caused by the fact that in thermal spectrum no isotope beside ^{233}U , ^{235}U , ^{239}Pu and ^{241}Pu has any significant fission cross-section.

Test mission

Neutron irradiation capabilities are a cornerstone to advancing nuclear R&D in particular with respect to new material development, fuel qualification, and life extension of the current fleets (NEAC, 2017). Most irradiation testing needs for existing reactors are met through a limited number of thermal-spectrum reactors. Given that those test reactors are operating with neutron flux of the same order of magnitude as that of current reactors, studying new materials and fuel behaviors at high irradiation levels takes a very long time. This is of particular importance for development of new reactor technologies, in particular fast spectrum systems, as this would require decades of irradiation in existing thermal-spectrum test reactors to achieve the desired irradiation level.

SFRs are uniquely suited to provide accelerated material and fuel testing capabilities as they are the most mature fast-spectrum reactor technology and can offer extremely high flux levels, large irradiation volumes, and significant experimental flexibility (Grandy et al., 2016). SFRs can easily deliver 30-60 dpa/year over large irradiation volumes, effectively speeding up material and fuel testing by a factor 10 or more as compared with LWRs.

While SFRs can deliver on several missions concurrently, the test mission stand somewhat apart from the others. Material and fuel testing can be hindered by power production operational constraints, and the reactor design itself is unlikely to be optimized for power production and testing capabilities at the same time. For instance, testing may require frequent outages, and a core configuration and operating temperatures different than those optimal for power production. Irradiation testing provision embedded in the design may further diverge from the power production mission.

Two SFRs being currently developed to tackle the testing mission are the MBIR developed by AEM Technology in Russia (Dragunov et al., 2012), and the Versatile Test Reactor (VTR) developed by the DOE-NE in the United States of America (Heidet, 2019). On paper, both reactors plan to offer similar flux levels, with peak fast fluxes in excess of $4 \times 10^{15} \text{ n/cm}^2\text{-s}$, but the MBIR design is more compact than the VTR one due to its reliance on fuel containing a very large fraction of fissile materials while the VTR will rely on low fissile contents and also offer larger available testing volume.

Fig. 15 Representative plutonium and minor actinides accumulation in thermal and fast spectrum systems.

Radio-isotope mission

SFR can also be used to produce radio-isotopes. This is effectively leveraging the same mechanisms as at play with transmutation, making use of excess neutrons to convert target materials into the isotope of interest. Looking at the world of experimental, research and test reactors, production of radio-isotopes has allowed several of these reactors to sustain operations through operational cost recovery. Sales of radio-isotopes has been a major contributor to offset the operational costs without significantly impacting the primary mission of those facilities (NEA, 2012).

SFRs having different flux and spectrum conditions than thermal-spectrum reactors, they are able to produce different radio-isotopes. SFRs typically have fluxes order of magnitude higher than thermal-spectrum systems, have the ability to tailor the neutron energy to a particular production need, have their core performance mostly unaffected by irradiation targets, and can have large volumes available for target irradiation. These characteristics make them uniquely suited for radio-isotope production (Schenter and Myjak, 1987). However, with only few SFRs around the world, this potential is mostly untapped at this time. Furthermore, unique radio-isotopes that can be produced in a SFR (e.g., alpha-emitters) do not yet have extensive commercial applications. This is for the most part due to the inability to produce them in reactors currently used for radio-isotope generation.

While it has not been determined whether or not a SFR dedicated solely to radio-isotope production could be commercially viable, many fast reactor concepts currently under development are considering incorporating capabilities to support radio-isotope production.

Future SFR outlooks

With the growing interest around the world in building advanced reactor systems, SFRs are at the forefront of it. The versatility of the missions that can be efficiently tackled with this reactor technology, its high maturity, and the safety benefits have led several countries around the world to plan design and constructions of SFRs. For some, as part of bridging experimental gaps, for others as a mean to keep up with the growth of their nuclear capacity and associated fuel resources utilization, and yet for others as a mean to advance their reactor technology to the next stage.

While SFRs are not yet commercially deployed world-wide, several commercial companies have been working on various types of SFRs, offering reactors ranging from large-scale units for electricity production all the way down to micro-reactor size for remote applications. Among the various designs of SFR there exists a specific category, called Breed and Burn reactors (B&B), which offer an innovative way of managing fuel loading in order to completely circumvent the need for fuel enrichment, after the very first fuel loading as well as avoiding used fuel reprocessing (Hejzlar, 2020; Qvist, 2021). These B&B reactors have gained significant traction over the last decade as they would enable achieve maximal resource utilization without the need for fuel separation, which still remains a highly political matter.

Although SFRs have demonstrated significant benefits over the current generation of nuclear reactor in use, there exist several challenges slowing down their widespread deployment. One of those major challenges is the unknown and uncertainties surrounding the capital and operating cost of SFRs (Mooz and Siegel, 1979; Kim et al., 2013). While most cost comparison studies

conclude that the capital cost of SFRs would be more than that of LWRs (Till and Chang, 2011), valuation of the benefit offered by SFRs is impossible without corresponding policy changes. For instance, this includes how we value resource utilization, amount of waste generated, sustainability, safety behavior, and other such consideration that are significantly enhanced by SFRs.

Another challenge faced by SFR is the political and public acceptance. Some of the technologies and capabilities enabled by SFRs, such as fuel reprocessing and breeding, are suffering from a stigma in the view of non-experts. In the past, this led to the early cancellation of the IFR project (Till and Chang, 2011) and early closure of the Superphenix reactor. With communication efforts over the last several decades, those stigma are slowly shifting away, but some still remain as they require more in-depth understanding to dispel. For instance, some decision makers are challenging the safety behavior of a reactor by requiring that each of its reactivity coefficient will be negative, while in practice one needs to look at the compounded effect, as discussed above in this article. Such miss-interpretation leads to forcing design choices onto the experts, potentially resulting in a more complex and expensive reactor.

At a higher level, SFRs are facing global challenges common to all advanced reactor technologies. There is a lack of market opportunities in many countries which already have a fleet of nuclear reactors and the energy demand of most of these countries is flat and no new power plant construction is warranted. Additionally, most countries do not have a fully established licensing framework for advanced reactors, which complicates moving advanced reactor projects forward and results in an increased risk for investors. Those challenges are being tackled and progresses made (GIF, 2018; U.S. NRC, 2018).

From the technical perspective, a pending item needing attention for commercial deployment of SFRs is fuel qualification. Even when uranium oxide is used, the condition experienced in SFRs are much different than in LWRs and therefore the fuel needs to be carefully qualified for these conditions. As it can include high burnups, the shortage of fast spectrum irradiation facilities across the world creates a bottleneck to fast reactor new fuel development and qualification. In addition to the relatively large fuel irradiation databases (Yacout et al., 2017) accumulated through operation of SFRs, efforts to develop very high flux irradiation facilities are underway in Russia through the MBIR project (Dragunov et al., 2012), and in the United States through the VTR project (Heidet, 2019).

Lastly, it is important to note that a number of studies focusing on non-reactor aspects of nuclear energy have concluded that fast reactors and in particular SFRs are the most essential reactor technologies with respect to various strategic objectives. For instance, an exhaustive fuel cycle study determined in 2014 that the most promising fuel cycles of the future will be based on fast reactor to enable resources sustainability and limited environmental impact (Wigeland et al., 2014, 2021). In 2017 the Advanced Demonstration and Test Reactor (ADTR) options study, carried in collaboratively by many institutions in the United States determined that SFRs were the most viable technology to offer accelerated irradiation testing capabilities (Petti et al., 2017; Grandy et al., 2016). Numerous additional studies across the world similarly point to SFRs being a keystone to advancing nuclear energy.

What is a high temperature gas-cooled reactor?

High Temperature Gas-cooled Reactors (HTR or HTGR) are helium-cooled graphite-moderated nuclear fission reactors utilizing fully ceramic fuel. They are characterized by inherent safety features, excellent fission product retention in the fuel, and high temperature operation suitable for the delivery of industrial process heat, in particular hydrogen production. Typical coolant outlet temperatures range between 750 °C and 850 °C, thus enabling power conversion efficiencies up to 48%.

The Very High Temperature Reactor (VHTR) is a longer term evolution of the HTR targeting even higher efficiency and more versatile use by further increasing the helium outlet temperature to 950 °C or even higher (Gougar, 2011).

From groundbreaking technology...

The HTR has evolved from the early gas-cooled reactors (GCRs) that gained widespread popularity for their simplicity and high power conversion efficiencies (Beech and May, 1999). The first commercial nuclear power plant was a CO₂-cooled graphite-moderated Magnox reactor (Calder Hall in 1956). In total, 26 Magnox reactors were built (270–1760 MWth), with the last one (Wylfa-1, 1971–2015) shut down at the end of 2015. As a second generation, 14 Advanced Gas-Cooled Reactors (AGRs) were deployed in seven nuclear power plants at six sites in the UK with a total capacity of approx. 8 GWe. All these AGRs are expected to remain in operation until 2023–30, although their life extension required clearance of graphite cracking issues and two power plants have to run at lower power because of the observation of cracks in boilers. This multi-decade effort in the development and operation of gas-cooled reactors allowed for collection of a considerable technical background and operational experience, which then served as the basis for the development of current HTRs. GCRs have an extremely clean primary cooling circuit (few radiological and chemical contaminants) and use a conventional steam cycle (~ 540 °C, same as for coal fired power plants) resulting in high thermal efficiencies (> 40%). However, GCRs had to observe a temperature limitation due to the dissociation of CO₂ and the resulting carburization of structural materials and oxidation of graphite at elevated temperatures. Modern HTR are characterized by increased operating temperature and thermal efficiency, which could be achieved by two major changes: the designs adopted helium as the cooling gas along with fully ceramic fuel, which is discussed in more detail in Section “**TRISO fuel: Key to performance and safety.**”

The first HTR was proposed in a 1945 design study in the US, but was never realized. It featured a primary circuit (helium at 1.55 MPa, 438–732 °C) coupled to a secondary Brayton power conversion cycle (air at 2.9 MPa, 677–22 °C) leading to an expected power rating of 5 MWe.

In 1962–63, a 3.3 MWth Mobile Low-Power Reactor (ML-1) with 140 (330 nominal) kWe was built in the US with a closed-cycle nitrogen turbine. The project was not pursued because it could not fulfill the power output expectations.

In 1964, the Experimental Gas-Cooled Reactor (EGCR) was built at ORNL in the US, but not completed. This was basically a helium-cooled AGR-type reactor using stainless steel fuel rod clusters. EGCR was expected to produce 85 MWth/25 MWe with helium at 566 °C.

Ensuing developments led to conceptual changes in the existing gas-cooled reactors involving, as mentioned, in particular the use of helium instead of CO₂, and the substitution of metallic fuel clads by fully ceramic fuel, both in view of a further increase of reactor outlet temperature and improved safety performance.

The first tangible step in this direction was made in the UK with the DRAGON reactor (see also Section “**Which HTR versions were developed?**”). With a power of 21.5 MWth, it was an OECD project and operated from 1964 to 1975 primarily as a test bed for HTR fuel development. It used already early versions of fully ceramic coated particles as its own fuel.

In the US, the Ultra-High-Temperature Reactor Experiment (UHTREX) operated at LANL from 1966 to 1970. Its rated power was 3 MWth using helium at 3.4 MPa (870–1300 °C). It used extruded fuel with TRISO coated particles in an annular rotatable core for on-line refueling.

More details on the development of HTR technology can be found in a recent authoritative summary (Kugeler and Zhang, 2019).

... to modern characteristics

The following developments led to basic technical characteristics and design features shared by all modern HTR.

- can be built with passive safety features up to 625 MWth/core (prismatic block type core) and 250 MWth/core (pebble bed core); this is the power range of Small Modular Reactors (SMR);
- long grace time after an accident (large heat capacity, low power density);
- self-stabilization of power transients (negative temperature coefficient);
- low source terms (outstanding fission product retention in robust TRISO coated fuel particles and structures);
- fully ceramic core (fuel and moderator/reflector);
- high-purity graphite as moderator/reflector, high thermal inertia;
- chemically and neutronically inert helium as primary coolant;
- high operating temperatures for high efficiency, capability for nuclear cogeneration of heat and power, including for bulk hydrogen production;

- high burn-up capability;
- high fuel utilization (good neutron economy and possible use of thorium).

There are two competing HTR designs based on the TRISO coated fuel particle (**Fig. 1**): the prismatic block core and the pebble bed core (**Fig. 2**).

- Invented by Peter Fortescue and his team at General Dynamics in the US, the prismatic block core is built from hexagonal graphite blocks containing vertical holes. Some of these holes are used for helium cooling, while others receive the fuel in the form of “compacts”, which are little cylinders (typically $\varnothing 12.3 \times 25$ mm) pressed from graphite and coated fuel particles (**Fortescue, 1975**).
- The pebble bed HTR was conceived in 1942 by Farrington Daniels in the US (**Daniels, 1944**). This early vision was later developed to a power plant design by Rudolf Schulten in Germany, which employed $\varnothing 60$ mm fuel spheres made of graphite and coated fuel particles (**Schulten et al., 1959**). These pebbles are filled into the reactor pressure vessel, which is internally lined with graphite blocks. The resulting pebble bed constitutes the reactor core. The pebble bed can flow and allows discharge and (re-)injection of pebbles during operation, enabling online refueling.

TRISO fuel: Key to performance and safety

One of the major challenges and key to achieving a fully ceramic reactor core was fuel development (**IAEA, 2010**). The initially used UO_2 or UC fuel was placed in ceramic clads which showed poor fission product retention. Coated particle fuel was invented between 1957 and 1961 by the United Kingdom Atomic Energy Authority (UKAEA) and Battelle, but no patent was granted at that time. The UO_2 fuel kernels were made by external gelation of uranyl nitrate in ammonia and, after a heat treatment, coatings were deposited on top of these kernels via pyrolysis of hydrocarbons in a fluidized bed. The next development step was the early BISO (bi-structural isotropic) particle fuel comprising a buffer layer directly deposited on the kernels and an additional pyrolytic carbon (PyC) layer on top. Finally, modern TRISO (tri-structural isotropic) particles were given an additional SiC diffusion barrier leading to confirmed fission product retention up to 1600°C or even higher (**Gougar et al., 2020**). These TRISO coated particles, typically in the order of 1 mm in diameter, are the basis for all modern HTR fuel designs (**Gerczak, 2021; Helmreich, 2021**). As shown in **Fig. 1**, they feature (from inside out) the kernel, a porous PyC buffer to accommodate fuel swelling and fission gases, a dense PyC buffer and a dense SiC layer as diffusion barriers against fission product escape, and a final PyC layer (missing in **Fig. 1**) for better bonding with the matrix graphite into which they will be integrated.

Baked into matrix graphite, the TRISO coated particles can now be given a macroscopic shape (**Fig. 2**), usually in the form of thumb-thick cylinders (“compacts”) either solid or annular, or in the form of spherical fuel elements (“pebbles”). The compacts are inserted into hexagonal blocks made of graphite, which are then assembled to constitute the reactor core contained in a pressure vessel.

Typical pebble and compact design characteristics are given in **Table 1**:

Which HTR versions were developed?

Based on these characteristics, in the 1960s two different types of reactors were designed and built, primarily to produce electricity. Experimental HTRs with a prismatic block core and TRISO coated particle fuel were developed in the UK (DRAGON reactor,

Fig. 1 SEM picture of a modern TRISO coated particle broken up to visualize the coatings; the top outer PyC layer is still missing on this particle.

Fig. 2 TRISO coated particle fuel as the basis for hexagonal block and pebble bed core designs (Gougar et al., 2020).

Table 1 Typical examples for nominal characteristic data of German AVR GLE-4 particles and pebbles and US NGNP particles and compacts.

Coated particle	AVR pebble	NGNP compact
Kernel composition	UO ₂	UCO
Kernel diameter [μm]	502	425
Enrichment [U-235 wt%]	16.76	14
Thickness of coatings [μm]:	92	100
buffer	40	40
inner PyC	35	35
SiC	40	40
outer PyC		
Particle diameter [μm]	916	855
Fuel element (FE)	Pebble	Compact
Dimensions [mm]	Ø60 (spherical)	Ø12.3 × 25 (cylindrical)
Heavy metal loading [g/FE]	6.0	1.27
U-235 content [g/FE]	1.00	0.18
Number of coated particles per FE	9560	3175
Volume packing fraction [%]	6.2	35
Fraction of factory defective SiC coatings	7.8×10^{-6}	$< 1.2 \times 10^{-5}$
Matrix density [kg/m ³]	1750	1600
Temperature at final heat treatment [°C]	1900	1850

operated 1964–1975, 21.5 MWth, an OECD project (Price, 2012) and in the US (Peach Bottom, operated 1966–1974, 115 MWth/40 MWe Beck and Pincock, 2011). They were followed by the prototype of the Fort St. Vrain Generating Station (operated 1976–1989, 842 MWth/330 MWe, Beck and Pincock, 2011). This reactor established the technical feasibility of HTRs although it experienced problems (Rempe, 2021) of power fluctuations, jamming of a control rod and leakage of moisture into the core, which finally caused its decommissioning for economic reasons.

Over the same period, Germany developed and built an experimental pebble bed reactor (AVR, 46 MWth/15 MWe, Pohl, 2008) at the Jülich Research Centre that successfully operated from 1967 to 1988 and produced valuable feedback on different types of pebble fuels and overall reactor operation. In particular, it was used for several demonstrations of passive safety performance. After a water ingress accident provoked by a steam generator leak it could be repaired, dried and returned to service. Following this experience, a 300 MWe prototype power reactor that aimed at using thorium fuel was built and operated: the Thorium High Temperature Reactor (THTR-300, 750 MWth/300 MWe, Baumer and Kalinowski, 1991; Dietrich et al., 2019). This prototype, however, met a number of technical difficulties. Examples of design issues are the direct insertion of the control rods in the pebble bed (causing

pebble damage) and the pebble discharge system, which allowed for jamming. The THTR was closed in 1989 in the aftermath of the Chernobyl accident after only 3 years of operation.

In the same period, the Power Nuclear Project (PNP-500, 500 MWth, Neef and Weisbrodt, 1979) started in Germany aiming at using nuclear heat to produce hydrogen by steam methane reforming. This project led to development and testing of large modules of heat exchangers and a steam reformer. It was brought to a halt in 1989 after the Chernobyl accident, which caused a temporary stop of HTR development worldwide.

In the 1980s, Interatom/Siemens in Germany developed the 200 MWth HTR-Modul as the first modular pebble bed design consisting of a metallic reactor pressure vessel connected to an adjacent steam generator through a hot gas duct (Siemens, 1988). The concept features a simplified design with a size and power rating chosen to enable passive decay-heat removal after a loss-of-coolant-accident solely by conduction and radiation. No natural or forced convection is necessary (Reutler and Lohnert, 1984; Kugeler et al., 2017). Although it was never built, the HTR-Modul has served as the basis for the PBMR in South Africa and for the HTR-10 and HTR-PM reactors in China.

The Gas Turbine Modular Helium Reactor (GT-MHR, LaBar, 2002) is a 600 MWth design developed by a group of Russian and US enterprises, Framatome in France and Fuji Electric in Japan. It was based on the earlier MHTGR-350 design by General Atomics. It employs an annular **prismatic core** and utilizes a direct helium **Brayton cycle** for electricity generation with an efficiency of up to 48% based on a reactor outlet temperature of 850 °C. Extensive analysis has shown that this reactor, and more generally most HTR designs, are particularly suitable for the incineration of excess plutonium which became an issue in the US and in the former USSR for the implementation of the START I disarmament treaty in 1991. Hydrogen production with the Sulfur-Iodine (S-I) process was also envisaged. The Preliminary Design of the reactor plant and GT-MHR prototype power plant was completed in 2001. The GT-MHR regulatory process started in 2002 but was not completed. More recently, the GT-MHR design was proposed by General Atomics as one of the options for the US NGNP project until the NGNP Alliance expressed in 2012 a preference for the ANTARES concept (625 MWth) developed by AREVA (Lommers et al., 2012), based on the GT-MHR but with an indirect steam cycle. A smaller version (SC-HTGR, 350 MWth) equally with indirect steam cycle was proposed by AREVA/Framatome as well (AREVA, 2014). The GT-MHR was also the basis for the Japanese GT-HTR300 designed by JAEA (Kunitomi et al., 2004).

A review summary on the 7 built reactors (Dragon, Peach Bottom, Fort St. Vrain, AVR, THTR, HTTR and HTR-10) can be found in (Beck and Pincock, 2011). The experience of past experimental and prototype HTRs demonstrated their technical viability, however, they were not given the time to prove their economic competitiveness with LWR for electricity production. No further developments were to occur until the late 1990s when the interest in HTRs revived owing to the needs of low carbon high temperature heat supply for a variety of industrial processes.

One of these new projects was the Pebble Bed Modular Reactor (PBMR, Matzner, 2004) in the Republic of South Africa. PBMR Pty. Ltd. is a public-private partnership established in 1999 in response to threats of nation-wide power outages in South Africa and to initiate the development of a modular pebble-bed reactor with a rated capacity of 165 MWe. This design featured a thermal power of 400 MWth and a direct power conversion with a gas turbine operating with a helium outlet temperature of 900 °C. In June 2003 the South African government approved a prototype of 110 MWe for the utility Eskom on the site of Koeberg. This prototype was intended to be put in service in 2014 and expected to precede a fleet of 24 PBMRs so as to make up 4000 MWe out of the 12,000 MWe additional nuclear capacity planned by 2030. Large facilities dedicated to PBMR specific technologies testing were built in 2007: a "Heat Transfer Test Facility", a "Helium Test Facility", a "Pebble Bed Micro Model" and an "Electro-magnetic blower." A fuel laboratory developed manufacturing processes and quality assurance testing techniques in collaboration with NECSA and successfully manufactured coated fuel particles with enriched uranium in December 2008.

In 2009 the PBMR project, like other projects of nuclear equipment in South Africa, faced funding difficulties and had its business plan re-oriented towards the supply of industrial process heat, a difficult endeavor in a country with large coal reserves and no CO₂ emission limits. The new focus of the PBMR was on onsite power, cogeneration, seawater desalination and direct process heat delivery. Target process heat applications included coal-to-liquid or gaseous fuels, petrochemicals, ammonia/fertilizer, refineries, steam for oil sand recovery, bulk hydrogen for future transportation and water desalination. Thus, PBMR Ltd. started developing options for commercial fleets with Sasol (the South African coal liquefaction company), with the utility Eskom for electricity, as well as with US and Canadian cogeneration end users including oil sand producers. The PBMR project was accordingly revisited to develop one standard design that meets all requirements for these applications, thus leading to a cogeneration steam plant with a power of 200 MWth, a helium temperature of 750 °C at the core outlet and a steam generator directly placed in the primary loop. A conventional subcritical steam turbine was selected for first generation plants whereas super-critical cycles were envisaged for next generation plants.

Due to funding issues and problems in the interaction between PBMR and the South African regulator the project was stopped in 2010. This development was analyzed critically in (Thomas, 2011). Another investigation with negative conclusions from operational performance of HTR in the past with a pessimistic outlook is summarized in (Ramana, 2016).

Since then, the aforementioned technological problems encountered with test reactors (e.g. moisture leakages into the core) have been solved to a large extent, so that most recent HTR designs could be deliberately geared towards short-term realization with minimum R&D efforts and development risks. In addition, with a much longer-term view, a number of research organizations cooperate internationally on the Very High Temperature Reactor, which is usually understood to produce heat above 950 °C to maximize power conversion efficiency and to enable ambitious process heat applications such as thermochemical hydrogen production with the S-I cycle. The VHTR is thus a long-term concept requiring new materials and design codes along with fuel qualification for the higher temperatures. The very significant progress of this cooperation is summarized in (Fütterer et al., 2014).

Recent results from test reactors

In the 1990s, the Japan Atomic Energy Agency (JAEA) built a research reactor in Oarai, the High Temperature Test Reactor (HTTR, (Kunitomi, 2013), Fig. 3). It is a prismatic block type reactor with annular compacts. It was put in service in 1998 and reached its full design power of 30 MWth in 2001 with a helium outlet temperature of 850 °C. Subsequent tests until 2010 have demonstrated the safe behavior of the reactor. This included reactivity insertion as well as partial and complete loss of forced cooling, but not yet at full power. The HTTR was successfully operated at the design temperature of 950 °C first in 2004, then for 50 continuous days in 2010. In parallel with tests on the HTTR, JAEA is developing the S-I thermo-chemical process to produce hydrogen (Fig. 4). A first demonstration of this process was achieved in 2003 when a continuous production of 30 l/h of hydrogen was maintained for several days. During the March 2011 earthquake, which triggered the Fukushima accident, the HTTR was only slightly damaged. After extensive inspection, some repair and after the review by the regulator, a restart is planned for 2021, pending a positive outcome of the public hearing. JAEA intends to conduct further safety tests in the frame of an OECD-NEA Loss of Forced Cooling Project.

Fig. 3 External view of the HTTR building in Japan.

Fig. 4 Schematic of HTTR and future heat use facilities.

Fig. 5 External view of HTR-10 building in China and Control Room.

The Institute of Nuclear and New Energy Technology (INET) of the Tsinghua University in China has built the experimental reactor HTR-10 (10 MWth) (Dong, 2012; Wu et al., 2002; Fig. 5) that was put into service in 2000. The successful operation of this reactor demonstrated an updated pebble bed core HTR technology. In particular, it served as a test bed for fuel, components and for code validation. The HTR-10 was also employed for district heating of the INET campus in the vicinity of the reactor. With several successful demonstrations of its benign safety performance for the public and the licensing authority it paved the way for scaling up this technology to the High Temperature Reactor – Pebble bed Module (HTR-PM, 210 MWe) project (Zhang et al., 2016).

Together with their predecessors, HTTR and HTR-10 have significantly contributed to the establishment of the rather high technology readiness level both for block type and pebble bed HTR designs.

The case for new next generation HTRs

Why have past HTRs not been successful economically and why do we think that this is changing?

GCRs were developed worldwide, but only the AGRs in the UK remain in commercial operation. After reasonable experiences with the first HTR plants in the UK (Dragon), the US (Peach Bottom Unit 1) and Germany (AVR), national HTR programs ended with no commercial deployments for various reasons. In the UK, the Thatcher government decided to build PWRs essentially because of absence of confirmed economic data for other designs, higher perceived financial risk of HTR designs compared to the mainstream PWR, and because of the then unsolved difficulty to integrate the HTR into a long-term sustainable closed fuel cycle that included Fast Breeder Reactors and reprocessing. In Germany, AVR was shut down in 1988 due to public opposition to nuclear energy, shortly after the Chernobyl accident. In the US, poor capacity factors of the Fort St. Vrain demonstration plant led to its premature shutdown in 1989. This has coincided with the time period of three decades without new nuclear orders in the US starting with the Three Mile Island accident in 1979.

In general, most HTR operational issues were associated, as already mentioned, with leakages, e.g. moisture ingress that resulted in corrosion of components, core temperature oscillations caused by coolant flow bypass and in-core behavior of graphite (cracking, dimensional changes, movement of blocks and distortions, dust formation) (Beck and Pincock, 2011). Most of these were first-of-a-kind operational issues and took a long time to resolve without the benefit of the broader industry experience that is dominated by water-cooled reactors. As a result, it led to poor performance in some HTR reactors, most notably the Fort St. Vrain reactor in the US.

On the positive side, however, the operational experiences with HTRs showed excellent fuel performance and demonstrated the concept's inherent safety features. Many lessons learned through past HTR experiences led to improvements in modern HTR concepts, such as the use of magnetic bearings in the helium circulator, or the use of a steel pressure vessel for improved reliability instead of a pre-stressed concrete vessel. Passive cooling systems, requiring no pumps or monitoring systems to initiate them, have been adopted. The excellent performance of TRISO fuel is further improved by recent extensive research programs (Electric Power Research Institute, 2019), which benefitted both fuel types, compact and pebble. These developments eliminate major known issues experienced by early HTRs and further corroborate HTR safety characteristics.

Ongoing HTR development

The last decade has seen significantly growing interest worldwide in Small Modular Reactors, which the IAEA defines as units producing less than 300 MWe. A snapshot of the very dynamic SMR landscape is given in (IAEA, 2018). These reactors are being designed by several classical vendor companies and start-ups for flexibility, affordability, for a wide range of users and applications,

Fig. 6 Artist's view of a 4-pack modular HTR for process heat, hydrogen production and electricity generation (INL).

and to replace fossil generation plants including in off-grid areas. These advanced reactors are deployable either as single or multi-module nuclear power plants, and are designed to be built in factory workshops and shipped to utilities for installation as demand evolves. **Fig. 6** shows how a multi-module pack could be configured to polygenerate heat, hydrogen and electricity.

Several designs ensure enhanced safety performance through inherent and passive safety features as well as suitability for cogeneration and non-electric applications thus opening opportunities for hybrid energy system architectures combining nuclear, fossil and renewable energy carriers. They have reached different stages of development and target near-term deployment with several vendor companies participating in feasibility and licensing studies.

About 16 of these SMR designs are HTRs with one currently under construction and commissioning in China (HTR-PM). Several of these reactors are derivatives or evolutions of earlier parent concepts, e.g. the HTR Modul for the pebble bed designs and the MHTGR-350 (designed by General Atomics) for several prismatic block designs. For the HTR concepts in **Table 2**, publicly available design information can be found in (IAEA, 2018).

R&D efforts as well as cooperation between all stakeholders (vendors, suppliers, regulators, utilities/end-users, investors, politicians, public etc.) are ongoing and organized at different national and international levels including GIF, IAEA, OECD-NEA, and are including economic analyses, as well as novel investment options and licensing approaches, e.g. (Gougar et al., 2020; Kalilainen et al., 2019). While the nuclear accident in Fukushima in 2011 has dealt a blow to nuclear energy development for several years, the ongoing debate about climate change mitigation has created new interest in low-carbon technologies in several countries and specifically awareness of the need to address the massive energy requirements of the process heat market in industrialized countries. As shown in **Table 2**, interest in the inherently safe, highly efficient and versatile HTR technology is steadily growing, and new

demonstration projects, in particular for the coupling of the nuclear reactor with a process heat end-user installation, are being implemented to help de-risk (and possibly shorten the time to) industrial deployment.

Beyond electricity: Emission-free process heat and cogeneration

Because HTRs are particularly fit for process heat applications and cogeneration of heat and power, this section is dedicated to non-power utilization aspects of nuclear energy, which has very significant potential impacts since it reduces fossil fuel consumption in areas beyond the electric power market, and thus enhances energy security, further increases the reduction of noxious emissions, and helps mitigating climate change. Already with earlier reactor types, nuclear cogeneration was performed in many countries and with several types of reactors including Light Water Reactors (LWR), Heavy Water Reactors (HWR), and Sodium Cooled Fast Breeder Reactors (SFBR). District heating (80–150 °C) is probably the most widely found application of nuclear heat: 46 reactors in 12 countries, including for instance Slovakia, Switzerland, Russia and China were and are used for this purpose.

Examples for low temperature applications of nuclear heat include seawater desalination (Japan, Kazakhstan), paper and cardboard industry (Norway, Switzerland), heavy water distillation (Canada), or salt refining (Germany).

The technology options for nuclear process heat utilization with HTRs were already documented quite early (Schulten, 1976). A survey of two decades of activities in Germany is given in (Verfondern, 2007a), and further potential is outlined in (Verfondern, 2007b).

The HTR produces heat at a much higher temperature level (exergy) than the LWR. This opens the possibility to replace a large number of existing industrial cogeneration plants delivering process steam in the 500–600 °C temperature range. Very significant amounts of such process steam are consumed in the chemical and petrochemical sector as well as in the fertilizer industry, where today this steam is mostly produced by gas or coal firing.

For several stakeholders, in particular in those countries where natural gas is expensive, the prospect of hydrogen production continues to be the main driver for development and potential deployment of the HTR and VHTR. Process heat from an HTR can be used for several more or less advanced methods of hydrogen production. The most near-term option is steam methane reforming of natural gas with steam at 700 °C, 5.5 MPa. Owing to the external heat supply, more than a third of natural gas is saved. In the 1980s, the necessary components, e.g. heat exchangers or reformers, were developed and tested under nuclear conditions in Germany and in Japan (Harth et al., 1990).

Processes and components for allothermal and steam coal gasification processes were also tested in Germany. They require typically steam in the range of 750–900 °C at 0.1–4 MPa. Although external heat supply makes coal upgrading more efficient, these processes release large amounts of unwanted CO₂.

These activities were brought to a temporary halt in an anti-nuclear climate after the Chernobyl accident, with inexpensive oil and gas and in absence of CO₂ emission restrictions.

As steam methane reforming to produce hydrogen consumes natural gas and generates CO₂ emissions in the process, direct water splitting methods are under investigation in several countries as a clean alternative. HTRs can provide steam for a rather low temperature process, the copper-chlorine (Cu-Cl) cycle, requiring steam at just over 500 °C (Rosen et al., 2012). Other prominent hydrogen production methods are (i) High Temperature Steam Electrolysis (750–950 °C) where a part of the required water dissociation energy is delivered in the form of heat, and (ii) thermo-chemical cycles such as the Sulfur-Iodine Cycle where one of the three process steps (SO₃ decomposition) requires heat input at 850 °C (Yan and Hino, 2011). This process is particularly suitable for VHTR operating at 900–1000°. The market for bulk hydrogen is currently very large and growing fast, with distribution networks already in place in several countries. To justify large-scale production of hydrogen, the development of a specific “hydrogen economy” is not required. Hydrogen uses include upgrading of increasingly heavy oils to lighter fractions, hydrogenation processes, hydro coal gasification, metal refining, ammonia production for fertilizers, the synthesis of methanol or synfuel, or the use of hydrogen in combination with fuel cells as a transport fuel. For some Asian countries, the replacement of coke by hydrogen for direct iron ore reduction is of particular interest to cut back emissions from steel making. Finally, hydrogen can also play a role in carbon capture and utilization processes, which would use CO₂ together with hydrogen as a feedstock for the fabrication of a wide array of possible products ranging from plastics or synfuel for aviation to construction materials. A summary of such processes and products is provided in (Styring et al., 2011).

In the context of energy system integration efforts with growing fractions of variable renewable electricity in many countries, it is of particular interest that the cogeneration capability of HTRs would allow it to contribute to grid stabilization (“peak shaving”), e.g. by modulating the production of (storable) hydrogen depending on the electricity demand in the grid, similar to what is currently envisaged for wind energy (“power to gas”).

To further corroborate the incentive for process heat and hydrogen production with nuclear energy, several market research, economic analyses, trade studies, and business plans were recently prepared in several countries, some of which are publicly available (e.g. Angulo et al., 2012; Bredimas, 2012; INL, 2012; Konefal and Rackiewicz, 2008; Shropshire, 2013).

Outlook

The unique capability of the HTR to produce process heat above 600 °C makes it an efficient reactor type to displace fossil fuels in various applications such as producing electricity, non-conventional hydrocarbon fuels from coal or biomass, and process heat for

Fig. 7 Installation of RPV into HTR-PM reactor building in 2016.

energy-intensive industries (oil refining, petro-chemistry, oil sand recovery, chemistry, steelmaking, etc.). Several market studies confirmed the potential for the HTR system to be used in such applications while the economic boundary conditions (e.g. price of natural gas, CO₂ tax) for market deployment have become clearer. The inherent safety characteristics of the HTR are a precious asset in contributing convincing answers to today's concerns in terms of nuclear safety, energy security, and climate change.

Current research performed within frameworks supported by GIF, IAEA and OECD-NEA, as well as specific national programs address primarily issues related to R&D, licensing, demonstration, and deployment. In particular, the multinational cooperation within GIF (GIF, 2018) allows sharing efforts to advance the technologies and to accelerate development in view of licensing and deployment. Currently, cooperation on the VHTR within GIF focuses on development and qualification of (i) fuel, (ii) structural and functional materials, (iii) hydrogen production processes and (iv) computer tools. GIF has also produced guidance for (V) HTR designers, e.g. in the areas of sustainability, economy, reactor safety, non-proliferation questions or energy system integration. The cooperation is clearly geared towards producing licensing-relevant information across the signatory countries and has recently opened to closer interaction with competing designer and vendor companies. Furthermore, the experimental reactors in Japan (HTTR) and in China (HTR-10) offer unique opportunities to qualify technologies and design codes. The next hurdle towards deployment is being taken by China with the ongoing commissioning of the HTR-PM demonstrator (Fig. 7). Japan will perform further safety demonstrations on the HTTR.

Since 2002, the bi-annual International Topical Meeting on High Temperature Reactor Technology is the sole international conference with focus on HTR and process heat applications (<https://htr2020.org/>).

Although very substantial results were produced, in particular by the signatories of the GIF VHTR System Arrangement, funding opportunities for a demonstrator coupled with an end-user process will have to be found soon to capitalize on previous investments. Several such international initiatives are on the way. Their success will depend on how much and where nuclear will be allowed to contribute to climate change mitigation, be it for political and public acceptance reasons or for economic boundary conditions (cheap natural gas, CO₂ tax, financial risk).

Introduction

The Generation IV international Forum started its activity with the choice of six reactors reference systems, including the LFR. These systems were identified as meeting the objectives of the “fourth” generation nuclear systems, viz. sustainability, safety and reliability, economic competitiveness as well as proliferation resistance and physical protection (Stanculescu, 2021; GIF, 2014a; GIF, 2018b).

At that time the design of modern reactors based on lead coolant was practically at its inception although some previous experience was already available. In fact, the use of lead or lead-bismuth coolants was proposed and investigated in the United States starting from 1942 and then abandoned around 1950 due to technological problems related to corrosion and coolant purification. In Russia however the investigation continued bringing to the realization of lead-bismuth cooled reactors for submarine propulsion in the 1960s (Zrodnikov, 2000). In the United States the interest for LFR systems was restarted thanks to the activities on Small Secure Transportable Autonomous Reactor (SSTAR) around 2000. In Europe proposals came out essentially in relation to Accelerator Driven Systems proposed for nuclear waste transmutation during the 1990s. During the Russian early and pioneering applications, the main aspects of the technology were investigated, and solutions identified to face technological problems related to the use of heavy metal coolants. Although some issues remain to be faced, the technology of LFR is becoming recently very attractive, and subject both to an increase of investigations and actors, thanks to some specific characteristics of the coolant and expected system safety performance. Several initiatives are taking place around the world and this article will briefly review them, providing references for readers interested in additional details.

Molten lead technology is today considered valuable for a number of nuclear applications: Lead cooled Fast Reactors are the most investigated application. Lead or lead-bismuth eutectic is also considered for transuranic elements transmutation, i.e. transmutation of plutonium and heavier elements accumulated in the nuclear fuel of light-water and other types of nuclear power reactors. This is typically achieved by neutron absorption in the transuranic elements in subcritical cores that are driven by protons

accelerators that generate neutrons by protons-induced spallation reactions (when very high energy protons or ions impinge on heavy-element targets like tungsten or lead, the spallation reaction will “knock-out” a number of neutrons); these systems are also called Accelerator Driven Systems. Lithium-lead is also proposed as a coolant and as a breeder of tritium (Coen, 1985) for fusion applications. After a description of the coolant characteristics, advantages and issues, a synthetic review of the main initiatives around the world is presented.

LFR and the goals of Generation IV

The objectives of the Generation IV International Forum are (Stanculescu, 2021): Sustainability, Safety, Economics, Proliferation Resistance and Physical Protection. LFR is expected to excel when challenged against such goals. The basic arguments are briefly summarized below.

Sustainability

The LFR, as a fast reactor system with its associated closed fuel cycle, is effective in fully utilizing the energy value of uranium. It is well known that fast reactor with closed fuel cycles can provide factors of up to 100 times greater natural uranium utilization than existing thermal reactor fuel cycles. This capability thus fully supports the first-Generation IV goal of increased sustainability. The neutronic properties of lead and lead-bismuth coolants (low neutron absorption and moderation) readily enable sustaining a hard neutron energy spectrum, providing good neutron economy and performance flexibility.

In order to achieve nearly 100% natural uranium utilization, it is necessary to reprocess the fuel after it reached its maximum permissible burnup (burnup is, effectively, the amount of energy that can be generated per unit fuel weight before the fuel has to be removed from the core) and recycle all the uranium and transuranic elements back to the core. The initial core must be loaded with fuel enriched with plutonium. However, after a few recycles the core reaches an equilibrium composition. In such “equilibrium mode”, the fuel composition at the beginning (end) of a cycle is the same as the composition at the end (beginning) of the previous cycle and either natural or depleted uranium is the only needed feed material as schematically illustrated in Fig. 1 (Artioli et al., 2010). The waste is made of only fission products as well as reprocessing and fabrication losses. Such a fuel cycle can be implemented as well in other types of fast reactors such as sodium-cooled (Heidet, 2021) and gas-cooled (Hatala, 2021) fast reactors.

Economics

Economic performance is generally difficult to quantify for new, advanced systems, yet there are several characteristics of LFR systems that suggest a potential in terms of economic performance respect to present Gen III or Gen III+ systems. Key among these characteristics are:

- the chemical nature of lead (or lead-bismuth) coolant, should it come in contact with air or water, guarantees the absence of strong interactions supporting the development of simplified and efficient designs that do not require complex, expensive intermediate coolant systems to isolate the primary coolant from the energy-conversion system (usually water) coolant.
- lead coolant retention properties of fission products are very important to reduce the source term and expected to enable a reduction (or possible elimination) of the emergency planning zone;
- the very high boiling temperature of the lead coolant (1749 °C) virtually eliminates coolant boiling and related safety challenges enabling further simplification of design and safety demonstration;
- the low partial vapor pressure of lead (2.9×10^{-5} Pa at 400 °C) allows primary system operation close to atmospheric pressure (as is also the case for sodium cooled fast reactors and molten salt reactors);
- the high operating temperature of LFRs enables high power conversion efficiencies, above 40%;
- the use of oxide and nitride fuels that can reach high burnup thus reducing fuel cycle costs;
- load following operations are strongly favored by the small difference between “cold state temperature” and operational temperature and the system can be coupled to an additional energy stored capability;

In summary, a good economic performance of LFRs can be expected due to the favorable inherent characteristics of the lead coolant.

Fig. 1 Equilibrium fuel cycle.

Safety and reliability

Increased safety and reliability of the next generation nuclear systems is becoming a major condition for public acceptance of nuclear power. Again, the basic and intrinsic characteristics of lead coolant plays an important role in terms of safety as well as reliability of the LFR systems. Following is a highlight of the most important aspects and consequences; a more detailed discussion can be found in (GIF, 2014b) and (GIF, 2020).

- high primary coolant boiling temperature protects the core against adverse neutronic feedbacks from voiding effects and protects the system against one of the possible initiators of a severe accidents. Only transient voids generated by cladding rupture and consequent fission gas release needs to be considered, but their effect will be naturally limited in time and value;
- thanks to the scattering properties of the coolant and its high atomic mass an LFR core can be designed with a large pitch-to-diameter ratio, providing enhanced safety against flow blockage and improved heat removal through higher natural circulation;
- LFR systems are not dependent on off-site power or emergency on-site back-up power thanks to their high thermal inertia and natural circulation capability enabling effective passive decay heat removal;
- the lead coolant provides a capacity for retention of volatile fission products, such as cesium and iodine, so that significant accidental release outside the primary coolant system is unlikely (Dubenkov et al., 2018);
- The potential energy stored in an LFR primary system is very low thanks to the relatively inert chemical nature of the lead coolant and the absence of hydrogen accumulation (Toshinsky et al., 2011), enhancing LFR's resilience in accident situations and facilitating the success of mitigation actions;

With respect to reliability, high levels can be achieved through design and extensive use of passive safety systems.

Proliferation resistance and physical protection

The last goal area for Generation IV systems aims at increased proliferation resistance and physical protection (PRPP). These characteristics are enhanced for LFR systems since:

- A common feature of fast reactor concepts with closed fuel cycle is the already cited sustainability, not requiring the generation/supply of additional enriched uranium, plutonium or other fissile material after reaching the equilibrium cycle.
- Some LFR concepts integrate/co-locate fuel reprocessing and fabrication functions into the reactor site so that, once equilibrium cycles are reached, only natural uranium is transported to the site as fuel feed, and only the relatively short-lived fission products leave the site for disposal;
- The possibility of long or very-long core life (and the corresponding increase of the time between refueling operations) reduces the proliferation risk associated with fuel handling operations.

For further insights on this topic the interested reader may consult the (GIF, 2021).

In summary, due to the potential for substantial improvements arising from the intrinsic characteristics of the coolant as well as from design and safety choices implemented in the considered LFR designs, in light of the technology advances and studies completed in recent years, it is appropriate to claim that the LFR operational and safety characteristics are meeting the GIF goals for the development of the next generation nuclear energy systems.

LFR design

LFRs designers have been facing from the beginning the novelty to work in a completely new environment (very different from lighter fluids) with the possibility to exploit as much as possible the specific characteristics of the fluid. Some early work, starting from the so called "loop" configuration, suggested immediately, due the weight of the coolant and associated seismic and supporting problems, to switch to the "pool" configuration with a primary side circulation organized inside a main vessel, and, in most cases, contained inside a safety vessel to prevent accidents caused by coolant leakages. However, such common characteristics have been declined in very different ways, thanks to engineer's innovation attitude and imagination. It is important therefore, before presenting general system arrangements and design solution, to highlight briefly the main coolant characteristics that can be used extensively in the design development.

Lead and in general heavy liquid metals are characterized by a very high density, 10 times higher than the water density. As a result, most of the pool immersed components are "floating" in the pool, so that they are normally "supported," i.e. pushed down, by the roof and not suspended. This fact generates some possible difficulties when trying to push some long elements inside the pool; the higher density is also limiting the maximum speed of lead coolant if we want to minimize erosion and maintain a dynamic pressure close to that of the water. Lead is also characterized by a high melting point (327 °C) and a very high boiling point (1749 °C). For lead-bismuth eutectic (LBE) the melting point is reduced to 123 °C with a boiling point still very high, 1670 °C. The high melting and boiling points introduce the need to consider the possibility of coolant freezing as well as practically exclude the existence of two-phase flow in the primary side, while the system pressure can be atmospheric, so no need of pressurization. The low vapor pressure provides some advantages since practically no evaporation takes place at the normal operating temperatures presently envisaged (2.9×10^{-5} Pa at 400 °C). Another very important characteristic is the low chemical reactivity

of lead with coolants like water or air. Since the oxidation reaction is slow, secondary side water coolant can be allocated directly inside tubes immersed in the primary pool, without the need of an intermediate loop. From a “nuclear and neutron economy” point of view lead has some very important advantages. As you can imagine such big nuclei are going to scatter the very small neutron particles in the core without absorbing energy during the collision process and, thanks to the low absorption cross section, the core can easily be designed as a breeder. This fact has important consequences in terms of the possibility to implement a closed fuel cycle. While its “neutronic” behavior is an advantage, it has also an important impact on the thermal hydraulic characteristics of the primary system. In fact, due to the scattering properties of such heavy nuclei, we are not forced to use packed fuel pins in our fuel assemblies. The pitch between the pins can be adequately spaced and designed to obtain very low-pressure losses in the primary system, in favor of natural circulation and of the overall safety characteristics. This fact induced designers to extensively use passive safety systems, as a natural way to promote an increased level of safety for such advanced nuclear reactors. The high boiling point of lead also has important effects on possible severe accident initiators related to coolant boiling reactivity void effects: they are considered highly unlikely due to the very high coolant boiling temperature, even in the case of loss of off-site and on-site backup power. Last, but not least, the lead coolant provides a capacity for retention of volatile fission products, such as cesium, iodine, and polonium, so that significant accidental release outside the primary coolant system is strongly limited.

LFRs areas of application

The possible areas of application of LFRs are very wide; as demonstrated by the growing worldwide interest, the possible sizes of LFRs range from the micro reactors to the whole range of small and medium reactors while future, longer term, options will cover also the large size reactors. Areas of applications are also strongly dependent from the maximum achievable primary side temperature and many efforts are dedicated by the international community to increase the operating temperature looking for maximum flexibility and efficiency of the thermal cycle. Apart from the obvious use of LFRs for electricity generation, with its primary cycle temperatures (depending on design) between 400 and 520–620 °C the LFR is highly compatible with solar thermodynamic plants (normally designed at 520–550 °C) and permit to explore possible synergies between nuclear and renewables.

In terms of flexibility the LFR presents important advantages depending essentially from the high “cold” temperature imposed by the lead melting point which limits in case of power modulation the temperature excursion. Practically speaking, if the primary flow is maintained constant, the primary temperature difference is roughly proportional to the power produced and for an LFR with a constant minimum cold temperature of 400 °C, only the “hot” structures are subjected to temperature excursion. These facts can greatly enhance the reactor flexibility allowing some degree of load following with important benefits in terms of electricity cost and revenues, although the preferred option in terms of flexibility is the introduction of energy storage, already introduced by some recent designs. With the suitable future increase of the hot temperature the LFR may be used also for hydrogen or industrial heat production, extending further the range of applicability of the technology. Thanks to its high safety performance and low likelihood of environmental radioactive release LFRs can be sited relatively close to small towns and there are projects considering this technology to provide district heating grids. For additional information on economics aspects, flexibility of Generation IV systems (GIF, 2019).

Research challenges

In the case of the LFR, the challenges include those related to the high melting point of lead; its opacity; coolant mass as a result of its high density; and the potential for corrosion when the coolant is in contact with structural steels. A specific challenge of the LFR is related to the high melting temperature of lead (327 °C) requiring that the primary coolant system be maintained at temperatures to prevent the solidification of the lead coolant. The pool type configuration and appropriate primary system design can provide effective solutions of the issue. The opacity of lead, in combination with its high melting temperature, presents challenges related to inspection and monitoring of reactor in-core components as well as fuel handling. Such issues can be addressed by appropriate and specific design features, for example, by innovative core configurations with the upper (non-active part) of fuel elements extended above the lead-free level (a choice pursued by some European designs). The high density and corresponding high mass of lead as a coolant are normally faced by structural design to prevent seismic impacts on the reactor system. Innovative primary systems configurations with short reactor vessels coupled with the introduction of seismic isolators are possible options to address such issues (EU 7FWP, SILER, n.d.). Perhaps the most significant challenges result from the tendency of lead at high temperatures to be corrosive, through a dissolution mechanism, when in contact with structural steels. This tendency, which is accelerated at higher temperatures, requires careful material selection and component and system monitoring during plant operations. Pending the development of new materials resistant to lead corrosion at high temperatures (e.g., for fuel cladding), approaches including anti-corrosion surface treatment of already qualified steels with careful coolant chemical (especially oxygen) control have been proposed to protect materials immersed in lead from corrosion (IAEA, 2019). In the presently proposed design configurations, a relatively low operating temperature strongly helps to reduce and practically eliminate the impact of this issue. The coolant purification needs to be carefully controlled and actively pursued in order to minimize deposits and the chances of flow blockages. The polonium issue (^{210}Po is a highly toxic alpha-emitter formed, in a reactor core, by neutron capture in the natural isotope ^{209}Bi) should be carefully addressed not only for LBE cooled system where the ^{210}Po production is very high, but also for pure lead systems due not only to bismuth impurities in the lead but also to double transmutation processes. Each of these areas of technology challenge is the topic of active ongoing research or is object of a specific provision at design level.

Finally, it is recognized that LFR fuel development can benefit from the vast data base and ongoing research being conducted for other reactor types, and especially from the Sodium Fast Reactor (SFR) fuel development activities. However, it is also recognized that where specific features of the LFR linked to irradiation conditions (i.e., linear power, temperature, neutron energies, fluence, and fuel-cladding interactions) differ from other reactor types, these differences need to be considered and addressed.

A reference LFR design: ALFRED

Following is a description of one reference LFR design, used as an example, to go through its main features in more detail.

Alternative design solutions will be described using cursive characters through the following ALFRED design description.

The Advanced LFR European Demonstrator (ALFRED) has been conceived in the frame of a European Commission funded project called LEADER from 2010 to 2013 (EU 7th Framework Program) (EU 7FWP, LEADER, n.d.). Sixteen partners were involved in the design activities and the reason for using it as a reference here is that most of the design details and data are public and so can be used by researchers without restrictions. ALFRED had been sized at 300 MWth, corresponding to 125 MWe and is cooled by pure lead. The configuration originally developed in the frame of LEADER project is used as a reference, further details on the actual design evolution will be presented as part of the following overview of LFR systems. A GIF webinar is available on internet on the ALFRED design solutions (GIF, 2018a, ALFRED webinar) and can be used to complement the information provided below. A previous webinar on the reference systems considered for activities of GIF System Steering Committee is also available (GIF, Lead Fast Reactor, 2017) and can be consulted to explore other possible solutions in more detail.

The configuration of the primary system is pool-type. This concept permits containment of all the primary coolant within the Reactor Vessel (RV), thus eliminating problems related to out of vessel circulation of the primary coolant (Fig. 2).

The Reactor assembly presents a simple flow path, with a Riser and a Downcomer. The heat source (the Core), located below the Riser, and the heat sink, the Steam Generators (SG), at the top of the Downcomer, allow for efficient natural circulation of the coolant. The primary coolant moves upward through the pump impeller to the vertical shaft, then enters the SG through the inlet holes, flows downwards on the shell and exits the SG to reach again the core.

The free level of the hot pools inside the Steam Generator and Primary Pump units is higher than the free level inside the cylindrical structure surrounding and supporting the core, the so called Inner Vessel (IV), Figs. 2 and 3, the different heads depending on the pressure losses across component parts of the primary circuit. The plenum between the primary coolant free levels and the reactor roof is filled by cover gas.

One of the basic characteristics of ALFRED primary system configuration is the primary pump being located in the hot region.

Other configurations exists as well, some of them are similar to SFR configuration with the pump located in the cold region with pressurization of the lower part of the core while in others the pump is used to elevate the cold fluid, before entering the SG, to generate the elevation head needed to balance the primary system pressure losses. Each system configuration presents advantages and disadvantages and the location of the pump in the primary flow path completely characterize and impact other design choices.

In the case of ALFRED, the RV is cylindrical with a toro-spherical bottom head. It is anchored to the reactor cavity from the top, by means of a "Y" junction (Fig. 2). A steel layer covering the reactor pit constitutes the Safety Vessel (SV).

Other types of vessel exist and will be highlighted in the following sections, while solutions using a main vessel surrounded by a safety vessel are also under investigation.

The dimensions of the gap between the SV and the RV are normally strongly conditioned by the size of the In-service Inspection tools. The SV mitigates the consequences of through-wall cracks in the RV with leakage of lead: any RV leakage is discharged into the SV. The RV and the SV are arranged in such a manner that, in case of a RV leak, the resulting primary coolant always covers the SG inlet and the lead circulation flow path is indefinitely maintained. The IV has two main functions: Fuel Assemblies (FAs) support

Fig. 2 ALFRED primary system: vertical (with primary flow path) and horizontal sections.

Fig. 3 Inner Vessel 3-D sketch, axial section and bayonet SG concept and arrangement.

and separation between hot plenum and cold plenum. It is fixed to the cover by bolts and is radially restrained at the bottom. Lead flow is guided from the FAs outlet towards the primary pump (PP) inlet pipes by a toroidal half-ring. Moreover, the pipes that connect the hot zone with the inlet of the PP are integrated in the IV. The cylindrical IV (Fig. 3) has a double wall shell: the outer thick wall has a structural function, while the inner thin wall follows the core section profile. The Core Lower grid is a box structure with two horizontal perforated plates connected by vertical plates. The plate holes are the housing of the FAs feet and the plate distances must be sufficient to assure the verticality of FAs. The lower grid is mechanically connected to the IV with pins. The Core Upper grid is a box structure like the lower grid but stiffer. It has the function to push down the FAs during the reactor operation. A series of pre-loaded disk springs press each FA to its lower housing. A hole is present for each disk to allow the passage of instrumentation (i.e., thermocouples, neutron detectors, etc.).

The steam generator and primary pump are integrated into a single vertical unit. Eight SG/PP units are located in the annular space between the cylindrical IV and the RV wall. The primary pump is placed on the hot side of the steam generator, having its mechanical suction in the hot pool inside the IV. The primary coolant moves upward through the pump impeller to the vertical shaft, then enters the SG through the lead inlet holes, flows downwards on the shell and exits the steam generator. The pump motor is located above the reactor roof. Each SG consists of a bundle of 542 bayonet tubes immersed in the RV pool for 6 m of their length. The bayonet tube is a vertical tube with external safety tube and internal insulating layer, composed of four concentric tubes (Fig. 3): a slave tube, an inner tube, an outer tube and an outermost tube. The internal insulating layer (delimited by the slave tube) has been introduced to ensure the production of superheated dry steam: in fact, without an insulating system, the high ΔT ($\approx 115^\circ\text{C}$) between the rising steam and the descending feedwater would promote steam condensation in the upper part of the steam generator. The gap between the outermost and the outer bayonet tube is filled with pressurized helium and high thermal conductivity particles (such as synthetic diamonds) to enhance the heat exchange capability. In case of an external tube break this arrangement guarantees that the primary lead does not interact with the secondary water. Moreover, a tube break can be easily detected by monitoring the Helium gap pressure. The Primary Pump is surrounded by the SG tube bundle, and its housing is the SG casing. The Pump is fixed to the top of SG casing by a bolted joint for easy removal of the component.

For what the SG units are concerned, several different possibilities have been explored and used by designers: helically coiled steam generators (already used for some advanced LWRs as well as SFRs systems), single bayonet tubes, plate heat exchangers, etc. Again, in the following overview of systems under development the different designers choices will be highlighted.

The core configuration (Fig. 4) is constituted by wrapped Hexagonal Fuel Assemblies. It utilizes MOX as fuel and uses hollow pellets and a low active height in order to improve natural circulation. The total power is 300 MWth. The core is made of 171 FAs, 12 CR (Control Rods) and four SR (Safety Rods), surrounded by 108 Dummy Elements ($\text{ZrO}_2\text{-Y}_2\text{O}_3$) shielding the IV. Each Fuel Assembly is about 8 m long and consists of 127 fuel pins, fixed to the bottom of the wrapper and restrained sideways by grids. Tungsten deadweight (Ballast) prevents buoyancy forces in lead. Upper elastic elements (cup springs) prevent lifting induced by hydrodynamic loads and accommodate axial thermal expansions. The FAs upper end extends beyond the lead free surface in the cover gas for easy inspection and handling. In this way it is possible to achieve refueling without the need of in-vessel refueling machines.

This solution is strongly characterizing the ALFRED design, other solutions have shorter fuel assemblies with blocking devices in the FAs lower part (foot) or an above core structure is provided to keep the elements in position. The choice is strongly connected to other design characteristics and the chosen design option strongly condition other design aspects.

The Decay Heat Removal system (DHR) consists of two passive, redundant and independent systems, DHR1 and DHR2, both composed of four Isolation Condenser (ICs), immersed in water pools, connected to four SGs on the secondary side (i.e., one IC for each SG). The system design considers the single failure criterion, since three out of four ICs are sufficient to remove the decay heat power.

The DHRs are dedicated safety systems, not used for normal operation. The separation is achieved by placing the two DHRs pools in physically different locations. A physical structural barrier or another means of protection will be placed between adjacent

Fig. 4 ALFRED core.

ICs to ensure that failure of one of them could not harm another one. The diversity requirement has been relaxed (in any case, two DHR systems will be fabricated by diverse manufacturers) due to the high redundancy and considering that the SG tube bayonet concept allows a continuous monitoring of the SG status.

Other systems and ALFRED itself in its new system configuration include a second DHR system using independent deep coolers.

Both systems are completely passive, with an active actuation through valves equipped with redundant and diverse energy sources (batteries or locally stored energy). Each DHR system must be ready to operate after the reactor trip in order to remove the decay heat power, in case of unavailability of the normal path (i.e., the by-pass to the Condenser). The actuation logic guarantees the actuation of DHR1 first, whereas the DHR2 actuates only in the case of failure of the first system. The total number of isolation condensers called to operate can never exceed the four units, in order to avoid an excessive cooling of the primary coolant leading to fluid solidification.

Each of the four independent IC sub-systems (Fig. 5) consists of:

- One heat exchanger (isolation condenser), constituted by a vertical tube bundle with an upper and a lower horizontal header.
- One water pool, where the isolation condenser is immersed; the amount of pool water is sufficient to guarantee 3 days of decay heat removal operation.
- One condensate isolation valve (to meet the single failure criterion, this function must be performed at least by two parallel valves).

Fig. 5 ALFRED DHR scheme.

Each IC is connected to a SG: the upper header of the IC is connected to the main steam line and the lower header of the IC is connected to the main feed water line.

In normal operation, the isolation valve below the condenser is closed, the condenser is full of water and no heat exchange takes place. As the IC subsystem is called to operate, the feed water line and steam line are isolated, and the condensate isolation valve opens. The subcooled water stored in the IC tube bundle drains into the SG, due to the hydrostatic head existing between the reactor and the IC. The IC tubes and headers become empty and their internal cold surface starts the steam condensation and hence to transfer heat to the cold pool water. The steam condensation causes a pressure reduction which calls for other steam from the SG. The water injected into the secondary system from the IC during the draining phase, vaporizes into the SG tube bundle contributing to the secondary system pressure rise: the safety relief valves continue to operate to reject to the atmosphere the excess of steam and to guarantee a secondary side pressure of 195 bar(a). When the IC reaches its steady state condition and starts to remove the thermal power from the primary coolant, the secondary side pressure rise decreases and finally stops leading to the closure of the safety relief valves on the main steam line.

For LFR designs the preference has been from the beginning to introduce passive decay heat removal systems thanks to the favorable characteristics of the lead coolant. The envisaged solutions possible are many and depend basically on the size of the reactor. For small sized reactors a so called Reactor Vessel Air Cooling System has often been used to remove the decay heat directly from the vessel wall through radiation, other systems (in the very small range) may use directly conduction through Vessel walls to provide cooling (with the disadvantage of having high heat losses in operation and the advantage of having no need of actuation). Of course, active systems can be used but the preferred way of introduction is their use as non-safety grade systems so that additional cost is eliminated (if passive systems are already available in case of loss of AC power). In case of pure lead systems and use of water as secondary fluid the use of boiling condition is practically mandatory due to the high temperature of the primary system. In case of LBE and lower temperature condition also the DHR pressure can be reduced and, in some cases, single phase conditions can be used. Other fluids can be considered such as diathermic oil or molten salt as well. They provide advantages in term of single-phase conditions, no or lower pressure but introduce problems related to coolant interaction with air (possibility of fires) and/or coolant dissociation or properties change over the range of allowed temperatures. In any case the design of DHR systems must consider the "freezing" temperature of the coolant in order not to impair the natural circulation of the primary side.

The Secondary System proposed for ALFRED is constituted by a steam-water cycle characterized by a turbine inlet pressure of 18 MPa, feed water entering the SGs at 335 °C and superheated steam at 450 °C. This is exactly the same cycle that was used for the sodium fast reactor Superphénix (SPX) and has an overall thermal efficiency greater than 40%. *Studies have shown that using supercritical water on secondary side does not provide a big advantage in terms of efficiency while supercritical CO₂ cycle are considered but must be the subject of further development before industrialization and should take into account the fact that they present a real advantage only at higher temperature conditions (over 700 °C).*

LFR development status and initiatives around the world

This part of the paper is far from being exhaustive but will try to give a brief overview of the present initiatives in different countries in both public and private sectors. We will try to cover both the pure lead and LBE technologies as well as the critical reactors and the ADS initiatives, starting obviously from the reference systems assumed as a basis for the Generation IV activities: BREST-OD-300 for Russian Federation, SSTAR for United States of America and ELFR for the European Community.

BREST-OD-300

The BREST-OD-300 reactor is a pilot demonstration reactor (300 MWe) considered as a prototype of future commercial reactors of the BREST family for large-scale nuclear plants characterized by the idea of "natural safety." It is the most advanced LFR design and the start of the construction is expected to take place in 2020. Fig. 6 provides an overview sketch of the BREST-OD-300 system. BREST-OD-300 (Figs. 6 and 7) is of pool-type design, which incorporates within the pool the reactor core with reflectors and control rods; the lead coolant circulation circuit with steam generators and pumps; equipment for fuel reloading and management; and safety and auxiliary systems. The reactor equipment is arranged in a steel-lined, thermally insulated concrete vault. BREST has a widely spaced fuel lattice with a large coolant flow area, resulting in low pressure losses, enabling the establishment of primary coolant natural circulation for decay heat removal.

It shares with other designs the absence of uranium blankets, replaced by lead reflector with the proper albedo improving power distribution, providing negative void and density coefficients, and ruling out the production of weapons-grade plutonium. The BREST decay heat removal systems are characterized by passive and time-unlimited residual heat removal directly from the lead circuit by natural circulation of air through air-cooled heat exchangers, with the heated air vented to the atmosphere. The fuel type considered for the first core of the BREST fast reactor is nitride of depleted uranium mixed with plutonium, whose composition corresponds to that of irradiated (used) fuel from VVER's following cooling and reprocessing. This mode of operation is characterized by full reproduction of fissile nuclides in the core (Core Breeding Ratio (CBR) ~ 1) with irradiated fuel reprocessing in the closed fuel cycle. Reprocessing is limited to the removal of fission products without separating Pu and minor actinides (MA) from the mix (U-Pu-MA). One of the notable characteristics of the BREST-OD-300 is that a reprocessing plant is co-located with the reactor, eliminating in principle any accident or problem due to fuel transportation. The main characteristics of this unique

Fig. 6 BREST-OD-300.

Fig. 7 BREST-OD_300 3D view.

demonstrator are a primary cycle between 420 and 535 °C, a power of 700 MWth, a superheated steam-water cycle reaching 505 °C at 170 bars, allowing for a thermal cycle efficiency of around 42%.

SSTAR

SSTAR is a small modular reactor (SMR) that can supply 20 MWe/45 MWth with a reactor system that can be transported in a shipping cask. Some notable features include reliance on natural circulation for both operational and shutdown heat removal; a very long core life without refueling; and an innovative supercritical CO₂ (S-CO₂) Brayton cycle power conversion system. Fig. 8 provides an overview sketch of the SSTAR system. The pre-conceptual design of SSTAR represents a small shippable reactor (12 × 3.2 m vessel), with a 15–30-year life open-lattice cassette core and large-diameter (2.5 cm) fuel pins held by spacer grids welded to control rod guide tubes. The main mission of the 20 MWe (45 MWth) SSTAR is to provide incremental energy generation to match the needs of developing nations and remote communities without electrical grid connections, such as those that exist in Alaska or Hawaii, island nations of the Pacific Basin, and elsewhere. Design features of the reference SSTAR, in addition to the lead coolant, 15–30-year cassette core and natural circulation cooling, include autonomous load following without control rod motion, and use of a supercritical CO₂ (S-CO₂) Brayton cycle energy conversion system. The incorporation of inherent thermo-structural feedbacks imparts a high degree of passive safety, while the cartridge core long life imparts strong proliferation resistance. It is presently a legacy system, not under continuing development, but is considered as representative concept, within GIF, of the “small-size” category of LFR developments.

The ELFR

The ELFR system is a modification of the earlier ELSY reactor concept. Fig. 9 provides an overview sketch of the ELFR reactor vessel and system arrangement. The ELFR primary system has a pool-type configuration, with the main vessels hanged by a Y-support holding the main vessel in the upper part. The reactor vessel has been kept as compact as possible, in order to reduce the coolant inventory and the corresponding seismic loads, while being of sufficient size to accommodate the required number of components (i.e., 8 Steam Generators (SGs), 8 Primary Pumps (PPs), and 8 Decay Heat Dip Coolers (DCs)). The hot pool of the ELFR vessel is enclosed by an inner vessel, connected to the PPs through suction pipes. Each PP is installed at the center of its corresponding SG, which transfers the heat from primary lead coolant to water-steam in a superheated cycle. The design is based on a core pressure loss of 0.9 bar and a total primary pressure loss of 1.4 bar. The core inlet and outlet temperatures are 400 and 480 °C. The internal reactor component arrangement and design presents a simple flow path for the primary coolant. The locations of the heat source (within the core) and of the heat sinks (SGs) allow for efficient natural circulation of the coolant under emergency shutdown conditions. Two safety systems for decay heat removal have been considered as an integral part of the design from the beginning of the activities. They are characterized by passive operation, diversity and redundancy while, in addition, being completely independent from one another. The design of the core has been driven by the implementation of the so-called “adiabatic” reactor concept, a closed fuel cycle approach (as above presented) maintaining constant the quantity of plutonium for no proliferation but supporting nuclear fuel sustainability.

Fig. 8 SSTAR conceptual sketch.

Fig. 9 ELFR concept.

ALFRED

In the description of ALFRED presented above the LEADER project design was used as a reference to explain solutions and differences with other systems. However, the ALFRED design is evolving thanks to the efforts of the so-called FALCON consortium trying to support the construction of the reactor in a relatively short time frame. The new system arrangement is a result of a design review which tried to identify the limitations and issues of the previous configuration. The main modifications can be summarized as follows: elimination of the vessel thermal stratification through a new primary system flow path defined by the use of a “hot” and a “cold” pool, use of single wall bayonet tubes in the SGs thanks to the new flow path design, three SGs, three primary pumps, three additional dip coolers connected to isolation condensers for a completely independent and diversified DHR-2 system, introduction of an anti-freezing system in the DHR concept. The new design has been presented recently in several conferences and journal papers the interested reader is referred to. Figs. 10 and 11 presents the reactor cover top view and the new primary system flow path. Falcon consortium also addressed the path to licensing through an innovative strategy in terms of R&D development, the so-called staged approach that foresees after the construction a progressive increase of operating temperature in order to qualify the structural materials and/or corrosion protection strategy in the lead coolant environment as well as prototypical irradiation conditions.

SVBR-100

The SVBR-100 is a multipurpose small modular fast reactor lead–bismuth eutectic (LBE) cooled with an equivalent electric power of 100 MW. In the Russian Federation, LBE cooled reactor technology has been used in several nuclear submarines (NSs). The experience (more than 80 reactor-years) gained was used in the development of the SVBR-100 reactor. The SVBR technology, according to its basic parameters and outstanding technical characteristics, is claimed as a Generation IV nuclear reactor. The entire primary equipment circuit of SVBR-100 including the reactor core, steam generators, circulation pumps and in-vessel radiation shielding is contained within a robust vessel of the reactor mono-block (see Fig. 12).

A protective casing surrounds the reactor mono-block (RMB). The reactor has negative void reactivity effect and negative temperature reactivity coefficient. Natural circulation of coolant in the reactor heat removal circuits is able to passively cool down the reactor for at least 72 hours preventing core temperature increase. Enhanced inherent self-protection and passive safety level, provided by the very high boiling point and chemical inertness of LBE, significantly simplify the reactor design as well as the entire NPP and improve the economy.

SVBR is a multi-purpose reactor and can be used for regional scale grids, industrial heat and desalination systems with the appropriate power levels (100–600 MW) depending on the specific needs. Reactor can operate with different type of fuel in different fuel

Fig. 10 Reactor cover top-view.

Fig. 11 Alfred primary system flow path.

cycles (period of operation without refueling not less than 7–8 years). At the first stage it will use typical uranium oxide fuel providing a core breeding ratio (CBR) of 0.83. MOX fuel can also be used, leading to a CBR just about 1.

Using UO_2 as the starting fuel, the closed fuel cycle can be realized in 15 years. Compact design and maximum factory readiness of the RMB are provided by its railway transportability and short construction time. The coolant technology system includes heat-exchangers, gas mixture ejectors, sensors of oxygen activity in LBE; its function is to maintain the LBE chemistry, inhibiting structural materials corrosion. The SVBR-100 reactor pursues resistance to nuclear fissile material proliferation by using uranium with enrichment below 20% while using uranium oxide fuel in the core.

Fig. 12 SVBR-100 reactor mono-block.

LFR-AS-200

The LFR-AS-200 (**Fig. 13**) is an innovative small reactor cooled by molten lead under development by Hydromine Nuclear Energy S.à.r.l., Luxembourg; AS stands for Amphora-Shaped, referring to the shape of the Inner Vessel (ASIV), and 200 represents the electrical power in MWe. The LFR-AS-200 is an integral, pool-type fast reactor with all the primary components installed inside the reactor vessel (RV). The main components of the primary system are six innovative Spiral-Tube Steam Generators (STSG), six mechanical pumps (MP), reversed-flag-type control rods, three + three Dip Coolers belonging to two diversified, passive,

Fig. 13 The LFR-AS-200.

redundant decay heat removal (DHR) systems and the ASIV, that is large in the bottom part in order to dispense of shielding assemblies. Thanks to the properties of lead, intermediate loops are not required. Because the STSGs are located within the RV, several special precautions deterministically eliminate any risk of important primary system pressurization in the case of tube rupture: among them water and steam collectors, located outside the RV, and short STSGs, partially raised above the lead-free level of the cold collector. The Fuel Assemblies (FA) are characterized by stems extending above the lead-free level with heads interacting to form a self-sustaining core. Refueling is performed under visual control and sealed conditions by means of two rotating plugs and an ex-vessel refueling machine. The absence of intermediate loops, the primary system specific volume of less than $1 \text{ m}^3/\text{MWe}$ and the compact reactor building, are key factors for a competitive kWh cost. The elimination of critical components like the in-vessel refueling machine, core strongback, and above-core structures immersed in lead, and hence submitted to thermal transients and fast neutron flux, reduces the need of In-Service Inspection (ISI) and increases the reliability of the plant. The design of the core aims at a system nearly self-sufficient in plutonium. The conversion ratio of about 0.9 is obtained without blankets.

CLFR

The CLFR series reactors (Fig. 14) are developed by the China Nuclear Power Technology Research Institute Co., Ltd. (CNNPTRI) as the next generation of commercial reactors of the China General Nuclear Power Corporation (CGN). The CLFR series include CLFR-100 and CLFR-300, developed to demonstrate the scalability of heavy liquid metal (HLM) cooled reactors. The CLFR-100 is a LBE cooled fast reactor with 100 MWe electric power, designed to demonstrate the technical feasibility of the small modular type HLM reactor with a target for operation by 2030. The CLFR-300 is a lead cooled fast reactor with 300 MWe electric power, designed to demonstrate the economic competitiveness of HLM cooled reactor relative to LWR technology. The CLFR series introduce advanced design ideas like the integral arrangement, modular design, whole core refueling, and smart operation and maintenance. The reactor primary system is an integral pool-type concept with all primary components arranged in the Main Vessel (MV), including the reactor core, steam generators (SGs), reactor coolant pumps (RCPs) and the internal structure. The integral pool-type design can provide safety advantages eliminating main vessel penetrations, reducing the likelihood of loss of coolant accidents (LOCA) and economic benefits due to simplification of the primary system. All primary components are designed to be extractable from the primary system for easy maintenance and replacement, with increased system reliability. A new safety concept named Natural Driven Safety (NDS) has been developed and applied to the design of CLFR reactors. The NDS of CLFR imply that the activation and operation of reactor safety systems are entirely driven by nature laws without the use of any active system (including batteries or electronic devices). Several specific NDS technologies are under investigation in CNNPTRI for CLFR reactors, including the Natural Driven Shutdown System (NDSS), the Natural Driven Decay Heat Removal System (NDDHRS), etc. The NDSS can virtually eliminate risks of unprotected accident while the NDDHRS can virtually eliminate risks of core damage and large release of radioactivity.

Fig. 14 CLFR sketch.

These excellent safety features can help CLFR reactors to improve both economic performance and nuclear power safety, ruling out the requirement of evacuation of the local population in case of accidents.

BLESS

A R&D project of a Lead-Bismuth Eutectic (LBE) cooled Fast Reactor named BLESS (Breeding Lead-based Economical and Safe System) has been implemented by State Power Investment Corporation Research Institute (SPICRI), the research institute of State Power Investment Corporation (SPIC) in China. In this project, the first reactor design is called BLESS-D (Demonstration) for the purpose of demonstrating the most mature and achievable technology of LFR in the near future. BLESS-D is cooled by LBE with thermal power of 300 MW while the electric power is set at about 100 MW. Fig. 15 provides an overview sketch of reactor primary system configuration of the BLESS-D candidate conceptual design. BLESS-D is a pool-type reactor in which the steam generators (SGs), pumps and reactor core are placed in the reactor vessel filled with LBE. The reactor core is centered and installed in an inner vessel. Two core designs of BLESS-D with UO_2 and MOX ($\text{UO}_2 + \text{PuO}_2$) fuel are proposed. UO_2 fuel is chosen in order to take the advantages of mature fuel-fabrication industry, while the MOX ($\text{UO}_2 + \text{PuO}_2$) fuel is chosen in order to obtain a longer life cycle and to reduce the long-lived high-level radioactive wastes. The core inlet and outlet temperatures are 340 and 490 °C. Eight once-through helical SGs and four pumps are arranged symmetrically between the space of inner vessel and reactor vessel in order to achieve forced circulation. Both water-steam Rankine cycle and supercritical CO_2 (S- CO_2) Brayton cycle energy conversion system are considered and designed for BLESS-D based on the technology capabilities of SPIC. Two types of passive decay heat removal systems with diversity and redundancy have been considered and designed from the R&D experience of the passive safety systems for large passive PWR in SPIC. The main goal of the 100 MWe BLESS-D is to meet the public demands of a safer, more flexible, more economical and more environmental-friendly nuclear energy system, especially for the energy demand from remote residential area and industrial area without national grid connection in China.

Westinghouse LFR

The Westinghouse LFR is a medium-output (~ 460 MWe), passively-safe, modular plant harnessing a lead-cooled, fast spectrum core operating in pool configuration and coupled with an air-cooled Supercritical CO_2 (s CO_2) Balance of Plant (BoP) system. The plant design results from business choices and technology solutions driven by the need to achieve competitive economics, versatility in future and diverse markets and high levels of safety at the same time, with baseload electricity production and load levelling as the primary plant's missions. The plant's output, selected based on economic considerations, is sufficiently small to integrate into lower-capacity grids while also being substantial enough to be used in standard baseload plant applications. Load levelling is achieved through an integrated thermal energy storage system using low-cost materials and coupled to existing BoP equipment, which allows load follow to be performed without requiring the core power to be varied. Moreover, being

Fig. 15 Conceptual design of BLESS-D.

air-cooled, the plant does not require vicinity to large water bodies, thus allowing for a greatly expanded variety of plant siting options. **Figs. 16 and 17** show a schematic of the primary system and of the plant layout, respectively. Reactor vessel compactness is promoted by the use of extremely robust, highly-compact hybrid microchannel-type primary heat exchangers and by the use of a water-assisted reactor vessel cooling system for emergency decay heat removal. This latter system allows removal of in-vessel deep coolers since, in case of accidents, it permits liquid lead natural circulation to be simply driven by passive heat transfer through the reactor vessel and guard vessel to an outer annular water pool. Transition to natural convection air cooling, circulating outside of the guard vessel, occurs when water is depleted. Fuel cycle flexibility is embedded in the plant design, with multiple fueling options and strategies being considered to satisfy market demand and customer preference. Starting with operation at lead temperatures up to $\sim 530^\circ\text{C}$, the plant is designed to transition to higher hot leg operating regimes through implementation of innovative materials

Fig. 16 Westinghouse primary system scheme.

Fig. 17 Westinghouse LFR plant lay-out.

currently being tested, for selected components that can be replaced while keeping the vessel and the majority of BoP components the same thus allowing the transition to occur at the same unit.

CANDLE

CANDLE reactor is a new concept of a lead-cooled fast reactor in which the fission burning wave moves in the axial direction of the reactor core (Fig. 18). Once a burning equilibrium state is reached, it requires only natural uranium or depleted uranium fuel feed. Details are provided by Prof. Sekimoto as part of this Encyclopedia.

Fig. 18 Neutron flux wave at the start-up of CANDLE reactor.

Lead cooled accelerator driven systems

Accelerator Driven Systems (ADS) consist of a high-power proton accelerator coupled to a subcritical nuclear reactor through a spallation target, generating the neutrons needed to reach criticality. For such systems the “neutron economy” is of great importance and this, together with the fact that the spallation reaction, in most cases, is provided by the impingement of the proton beam on a liquid metal target, makes the Lead or Lead-Bismuth the preferable coolants for this application. The goal and interest around this system, apart from the research interests, resides in its use for waste incineration, given the possibility to add to the fuel an important quantity of Minor Actinides without compromising the safety characteristics of the system thanks to the sub-critical mode of operation, intrinsically providing a “scram” when the proton beam is shut down. For further detailed information please see (IAEA, 2015).

MYRRHA

MYRRHA is the Multi-purpose hYbrid Research Reactor for High-tech Applications developed at SCK•CEN (in Mol, Belgium). It will demonstrate the accelerator driven system (ADS) concept by coupling the accelerator, the spallation target and the subcritical reactor at power levels capable of providing experience feedback which is scalable to an industrial demonstrator. In addition, it will allow the study of efficient transmutation of high-level nuclear waste (Fig. 19). The MYRRHA-facility is conceived as a subcritical flexible irradiation. It will also be able to work in critical mode albeit with different performance characteristics. Both modes of operation have their specific energy and flux distributions which permit a wide range of applications: from fuel development for innovative reactor systems; material development for GEN IV systems and fusion reactors, to radioisotope production for medical and industrial applications. Since MYRRHA is based on heavy liquid metal technology with lead-bismuth eutectic (LBE) as coolant, it can also significantly contribute to the development of lead fast reactor technology and will therefore play the role of the European Technology Pilot Plant in the roadmap for lead fast reactors (LFR). The MYRRHA reactor is a pool-type concept integrating all the primary systems in the reactor vessel. These include a diaphragm separating the hot and cold plenum, four primary heat exchangers, two primary pumps, two in-vessel fuel handling machines, and a core unit. The latter contains, among others, fuel assemblies, control rods, safety rods, the spallation neutron target, instrumentation and experimental devices. The reactor is located in the reactor pit which features a liner able to serve as secondary containment in case of a reactor vessel leakage or break. The reactor cover closes the reactor vessel and supports all the components. Because of structures above the core, the fuel and reflector assemblies have to be loaded from underneath. Thanks to the buoyancy, the fuel and reflector assemblies do not need locking devices to hold them on the core support structure. The cooling system of the reactor can remove up to 110 MWth in active mode. It is also designed to remove the decay heat in a passive way with quadruple redundancy. In case of a common mode failure of the cooling system, the diverse Reactor Vessel Auxiliary Cooling System can, in a passive way, take over the cooling function. The primary system operates at full power, that is, 100 MWth in critical mode or 65 MWth in subcritical mode, at a temperature range from 270 up to 325 °C with a flow rate of 13,800 kg/s LBE. In September 2018 the Belgian Government decided to support the construction in a phased approach of MYRRHA at the site of Mol, Belgium. In the first phase, budget is allocated for the construction of the first part of the accelerator up to 100 MeV including an ISOL (isotope separator on-line) and a proton target facility. This first phase, called

Fig. 19 MYRRHA—an accelerated driven system: coupling of accelerator, spallation target and reactor.

MINERVA, has to be finalized in 2026. In this first phase further design, R&D and licensing for the second part of the accelerator and the reactor is also being performed with the objective to obtain in 2026 the necessary permits for construction.

CLEAR-I

China Lead-based Research Reactor CLEAR-I is a 10 MWth reactor cooled by lead-bismuth eutectic (LBE). It was designed to be operated in a dual way: critical operation mode for technology test of lead cooled fast reactor and subcritical operation mode for ADS operation technology validation. The experimental objectives are expected to be achieved step by step, such as loading different types and amounts of fuel or adjusting the intensity of the proton beam, which will be carried out in the same experimental platform. CLEAR-I reactor is a compact pool type structure, which is composed of reactor vessel, reactor internals, vessel closure head, rotating plug system, reactor core and spallation neutron target, etc. The fuel assembly is composed of 61 fuel rods with triangular arrangement. The UO_2 with ^{235}U enrichment of 19.75% is chosen as the first loading fuel, and the cladding material is austenitic steel. A vacuum beam tube is placed in the center of the core unit which let a 250 MeV/10 mA proton beam enter from the top through the window to the flowing LBE target. The Core inlet and outlet temperature are 300 and 400 °C. The reactor vessel is designed as a double-walled pool-type vessel. The CRDM adopts the methods of counterweight and driving spring to overcome the descending resistance initiated from the high density of the lead-bismuth alloy. Double wall bayonet tubes for four primary heat exchangers are used aiming to reduce the risk of the heat exchanger tube rupture event. Two primary pumps are vertically installed in the cold pool. Reactor vessel air cooling system (RVACS) is designed to remove decay heat passively in accident conditions. Three integrated test facilities have been built at INEST (Institute of Nuclear Energy Safety Technology, HEFEI, China), the lead-based engineering validation reactor CLEAR-S, the lead-based zero power critical/subcritical reactor CLEAR-0 coupled with HINEG neutron generator and the virtual reactor CLEAR-V, to validate and test the key components and integrated operating technology of CLEAR-I. CLEAR-S is a large lead-bismuth pool-type facility with full scale height and 1/2.5 diameter with respect to CLEAR-I. The LBE inventory is larger than 200 t. The total heating power of the seven fuel assemblies simulators is 2.5 MWe. The prototype components test and integrated circulation thermal hydraulic test under steady and transient conditions are carried out to support CLEAR-I project (Fig. 20).

TORIA

TORIA, a ThO_2 -based subcritical burner naturally cooled by LBE has been designed to eliminate TRU produced in LWRs, leaving behind only low and intermediate level wastes. Thoria-based TRU-bearing fuels will be produced from advanced TRU extraction by PyroGreen of waste materials (Korea Atomic Energy Research Institute's pyro-processing). The spent fuels from TORIA can be continuously recycled by PyroGreen process while discharging low and intermediate level waste only. The Toria core consists of 162 thoria-based TRU-bearing fuel assemblies and 102 LBE reflector assemblies in hexagonal lattice. At the core center a spallation target channel about 15 cm in diameter is positioned for 590 MeV proton beam from a superconducting cyclotron with a separate LBE circulation system (Fig. 21). The overall height of the TORIA is 130 cm with a central active core of 70 cm height with keff of 0.99.

CiADS

The China initiative Accelerator Driven System (CiADS) is a transmutation research facility consisting of an accelerator, a spallation target and a sub-critical LBE cooled fast reactor. The initial purposes of this facility include: research on the strategy of the stable,

Fig. 20 CLEAR-I sketch and picture of CLEAR-S facility.

Fig. 21 TORIA conceptual design schematic.

reliable and long-term operation of the superconducting linear accelerator, high-power spallation target and sub-critical reactor; research on the interaction between systems during the coupling operation mode; breakthrough of the coupling technology under the full power operation mode. After that, the device will be operated as a comprehensive experimental platform to carry out the experiments on MAs transmutation and structure materials irradiation. Meanwhile, the special design software for ADS system will be developed in this project to support the development of industrial demonstration ADS facility in the next step after the end of the construction of CiADS. The total thermal power of the sub-critical reactor is 10 MWth (including the spallation target power). The reactor has been chosen as a pool type configuration, as shown in Fig. 22. From the figure one can see that there are two main coolant pumps and four main heat exchangers to remove the core power. The core inlet and outlet temperatures are 280 and 380 °C, respectively, which can effectively reduce the corrosion induced by the LBE. The secondary coolant has been chosen as molten salt so that it can be operated in the atmospheric pressure condition. During the core design phase, much more spaces have been left for the experimental devices installed in the future. The core decay heat can be removed promptly through natural circulation.

A forward look

The main goal of this LFR article was to highlight the benefits achievable through the development of the lead cooled fast reactor concept in terms of Generation IV goals. The interest in the technology is continuously growing worldwide covering a large number

Fig. 22 CiADS sketch.

of potential applications. What is necessary for advancement of this technology is the realization of one or more demonstrators. While this is already a reality in the Russian Federation, with the start of BREST-OD-300 construction activities, we hope that other Countries or the international community will be able to make the same step, bringing the LFR to industrial reality, for the deployment of this so promising technology in the middle of this century.

Acknowledgments

The author wishes to personally thank for the useful discussion and the work carried out with the whole group of the members of the Generation IV Lead Fast Reactor System Steering committee: K. Tuček, A. Moiseev, C.F. Smith, I.S. Hwang, J. Ming, Y. Wu, T. Obara, M. Kondo. The author also thanks all designers that provided the material for Chapters 4 and 5.

Introduction

Gas cooled fast reactors (GFR, GCFR) were subject of intensive studies and design activities in the 1960s and 1970s induced by the effort to cope with expected enlargement of nuclear power plant fleet and limited uranium resources. Together with liquid metal cooled reactors, the GFR were the preferred option. Presently, the fast reactors are gaining increasing attention for several reasons - mainly for their potential contribution to sustainable development by using a much larger fraction of the uranium resources; for the high number of excess neutrons available in a fast reactor which allows their application as actinide transmutation reactors, to reduce the long-term radiotoxicity of nuclear waste; and high temperature of the coolant, providing high thermal cycle efficiency and enabling co-generation of hydrogen and other industrial uses.

For fast reactors, the choice of coolant is dictated by the desire to introduce the smallest amount of absorption and moderation, while still being able to reliably remove the heat from the reactor core. Commonly a liquid metal is chosen, but a gas coolant is also possible.

The GFR cooled by helium is proposed as a competitive longer-term alternative to liquid metal cooled fast reactor ([Heidet, 2021](#); [Alemberiti, 2021](#)). It provides several attractive features. Helium is a single phase, chemically inert and transparent coolant. It does not dissociate or become activated, and in spite that the coolant void coefficient is generally positive, it is a comparatively small effect compensated effectively by negative Doppler and other reactivity feedback mechanisms. The high core outlet temperature above 750 °C (typically 800–850 °C) is an added value of GFR technology.

The advantages of a relatively simple system layout in GFRs, a potential of high breeding gain, and higher thermal efficiency are offset by the need of the engineered safety precautions for depressurization. In practice the temperature limits on conventional cladding material (stainless steel) do not allow operation at much higher temperature than in a typical sodium-cooled fast reactor. No GFRs were ever constructed, and the “classic” GFR concept was abandoned in the late 1970s.

During the next decades several conditions changed and GFR (as well as some other reactor concepts) are subject of restored attention and conceptual studies, reflecting both changes in energy market and advances in technologies to deal with gases and to produce refractory construction materials. The GIF Technology Roadmap (GIF, 2014) identified the GFR as a technology that associates the advantages of fast spectrum systems with industry needs.

Within the Generation IV framework the GFR targets sustainability, that is, optimal use of resources while maintaining good safety and economic performance. The reference design of the Generation IV GFR features the following (van Rooijen, 2009):

- Fast reactor core without fertile blankets, that is, all new fissile fuel is bred in the core. The background is that in a fertile blanket, the fissile element (e.g., Pu-239) is isotopically almost pure, which poses a proliferation concern.
- Breeding enough fissile material to refuel the same reactor, recycling all heavy metal, adding only fertile material; only fission products and reprocessing losses are discharged to a repository.
- The fuel specific power is comparatively low, typically around 40 W/gHM. By allowing a low specific power, the volumetric power density in the core remains limited, typically between 50 and 100 MW/m³, which ensures manageable safety characteristics.
- Helium is chosen as the reference coolant.
- The design of the core and fuel elements aims at promoting passive decay heat removal and providing adequate margins to core melt, by using refractory (high melting point) materials, and by allowing a large coolant fraction in the core.

The reference GEN IV concept for GFR is a 2400 MW_{th} plant operating with a core outlet temperature of 850 °C enabling an indirect combined gas-steam cycle to be driven via three intermediate heat exchangers. The high core outlet temperature places onerous demands on the capability of the fuel to operate continuously with the high power density necessary for good neutron economy in a fast reactor core. This represents the biggest challenge in the development of the GFR system. The second significant challenge for GFR is ensuring decay heat removal in all anticipated operational and fault conditions.

A necessary step in the development of a commercial GFR is development of an experimental demonstration reactor, to allow qualification of the refractory fuel elements and full-scale demonstration of the GFR-specific safety systems. The proposed demonstration reactor for the reference GIF GFR concept shall be the ALLEGRO a low power GFR facility (50–100 MW_{th}) with the ability to operate in different core configurations starting from a “conventional” core featuring steel-cladded MOX fueled pins, followed by all-ceramic fuel elements in the latter stages of operation.

History of GFR

In the following, there is a very brief overview of GFR projects worldwide. It is intended not to be exhaustive but only to illustrate those concepts which were subject of more intensive research and development in the past.

In 1962, General Atomics (USA) designed a prototype reactor with a rated power of 300 MW_e as well as a 1000 MW_e industrial-scale gas cooled fast reactor (GCFR) (IRSN, 2014). The detailed design and certification program for a 300 MW_e helium cooled high temperature prototype reactor began in 1965–66. This GCFR was designed to use fuel consisting of uranium and plutonium, with austenitic stainless-steel cladding. Helium entered the reactor core at a temperature of 385 °C and exited at 550 °C. The helium coolant pressure was 8.5 MPa, and the primary circuit was contained within a reinforced concrete shell. The core of the GCFR was very similar to those of sodium-cooled reactors, apart from the addition of equipment to distribute the helium supply to the base of the fuel assemblies and the adoption of ridged cladding to enhance the heat exchange with the helium. Development work for the GCFR continued until 1981, when development of fast reactors was abandoned in the United States.

In Europe (van Rooijen, 2009) a number of players in the nuclear field joined forces to establish the Gas Breeder Reactor Association for development of a gas-cooled fast reactor. This group proposed a first design (GBR-1) in 1970, a 1000 MW_e reactor featuring helium coolant, pin-type fuel, conventional outlet temperature, and a secondary steam cycle. This design was followed by GBR-2 and GBR-3 (1971), also 1000 MW_e reactors but using coated particle fuel, slightly elevated outlet temperature, and helium coolant for GBR-2; CO₂ coolant for GBR-3 (Chermaine (1972)). The design finally evolved into the GBR-4, a 1200 MW_e reactor with helium cooling and pin-type fuel.

The GBR-2 design is interesting because it resurfaces in modern design proposals for GCFRs, for instance, in Japan (Konomura et al., 2003). The objective of the coated particle fuels was to increase the core outlet temperature to improve the thermodynamic efficiency of the secondary steam cycle. For both GBR-2 and GBR-3 coated particles were only used for the driver fuel, the blankets employed traditional pin type fuel. This solution was chosen because, at the time of design, reprocessing of coated particle fuel was not proven. GBR-2 and GBR-3 required several ceramic parts, most notably the structures at the outlet side. The fabrication difficulties related to large ceramic parts led to the development of GBR-4, which is a much more conventional design. In GBR-4, the outlet temperatures are decreased, enabling the use of stainless steel components throughout the core. The plant efficiency is lower, which is offset by a larger total output of the reactor, elevated from 1000 to 1200 MW_e. A last reference to the GBR-4 design was found in Chermaine and Burgsmuller, 1980), where the safety case for large GCFR cores is discussed.

In the late 1970s, a UK program (van Rooijen, 2009) was initiated into an “Existing Technology Gas Breeder Reactor” (ETGBR). This design focused on joining the experience gained in the UK on sodium systems (Dounreay) and the thermal CO₂ - cooled advanced gas cooled reactors. The fuel assemblies used stainless steel cladding with surface roughening, while the entire system was to be housed in a concrete vessel as used for the advanced gas cooled reactors. ETGBR also used CO₂ coolant, and had a lower power density than Liquid Metal Cooled Fast Breeder Reactors (LMFBRs) (Kemish et al., 1982). The ETGBR was not very different from other designs of the same era for GCFRs. However, the ETGBR idea lingered on for a long time well into the late 1990s. At that late stage, the ETGBR was rebranded as the Enhanced Gas-Cooled Reactor which was proposed as an actinide burner, first within the European Fast Reactor program, and later in the CAPRA/CADRA study (Sunderland et al., 1999). By then, the reactor featured 3600 MW_{th}, CO₂ cooling, and nitride fuel in fuel pins.

In Japan (van Rooijen, 2009) a fast reactor program was initiated in the 1960s, including sodium and gas-cooled reactor concepts. Kawasaki Heavy Industries investigated GCFR concepts cooled with steam, CO₂ and helium (Mochizuki et al. (1972)). The helium concept was based on LMFBR technology, but opted for a very low core, to reduce the pumping power requirements. The flat core also increases breeding gain but requires a larger fissile fraction. Investigations into the GCFR concept seem to have continued without interruption in Japan, culminating in the late 1990s in a GCFR design proposal (Konomura et al., 2003).

GEN IV GFR design options

Besides the generic features of fast neutron spectrum reactors, which are common to all types of fast reactors, the GFRs provide some specifics resulting from light gas coolant. Helium (or some other gasses) complies with the requirement of the smallest amount of neutron absorption and moderation, while still being able to reliably remove the heat from the high power density configuration of the core. In comparison with sodium or other liquid metal coolants, gas coolants have the following advantages for fast reactor applications:

- Chemical compatibility with water and generally good chemical compatibility with structural materials
- No restriction related to operation temperature
- Negligible activation of the circulating medium in the core
- Optical transparency (which simplifies fuel reload operations and inspection)
- No pockets of coolant in cooled down fuel assemblies (compared to liquid metal reactors)
- No phase change in the core, reducing the potential of reactivity instabilities, particularly during transients and accidents
- Reduced (but still present) positive void feedback coefficient
- Potential for a hard neutron spectrum, which increases the breeding potential of the reactor
- Possibility to design core with increased neutron leakage, adding design flexibility in terms of improved breeding gain

Nevertheless, the gas coolant brings several challenges and potential disadvantages. They are mainly the following:

- More demanding means to keep coolant circulating in the system
- Need to maintain high pressure in the system, with associated challenges to prevent leakage of the coolant out of the system
- Low heat transfer coefficient from fuel to coolant, with impact on pumping power, gas velocities, requirements to peak fuel and rod clad temperatures, as well as higher peak-to-average fuel and clad axial temperature distributions (due to the reduced volumetric heat capacity of the coolant)
- High coolant flow velocity, which can lead to significant vibrations of the fuel pins
- Safe removal of decay heat from the high-power density core may be difficult

There are several additional specifics and limitations relevant to GFR, coming e.g. from restrictions placed on plutonium content, relatively very low thermal inertia of the core, capability of burning fission products and others. This is reflected more or less in present design options of individual components of the GFR.

Here below, the reference GEN IV GFR concept is described, based on a project developed by CEA until 2009 (RGN, 2014), with the design power 2400 MW_{th} (Fig. 1).

The fuel consists of pellets of mixed uranium and plutonium carbide ((U,Pu)C). The fuel element of the GFR concept is based on a refractory metal lined silicon carbide fiber reinforced (SiCf) clad pin. The pins contain a plenum in which fission gas can collect for the whole duration of fuel operation and other features to prevent pellet-clad interaction and reduction of the fuel cladding swelling. Fuel element design is based on refractory and high thermal conductivity materials, with the ability to ensure radioactive material confinement up to very high temperatures.

The core layout of the reference GFR concept has been chosen to be consistent with the maximum power derived from thermal-mechanical and thermal-hydraulic analyses, the requirements of the reactivity control system and the optimized power distribution. It shall allow fast neutron spectrum with a zero (self-breeding) or positive breeding gain, with no or very limited use of fertile blankets (due to proliferation concerns), to generate as much fissile material as it consumes, with an optimal use of uranium, to have a fuel cycle fed with only depleted or natural uranium and to achieve homogeneous recycling of all actinides, in order to allow operation without separation of plutonium from other actinides (again due to proliferation resistance considerations). Core plutonium inventory shall not exceed 10 tons/GW_e, in order to have a realistic reactor fleet deployment (in a few decades) and high fuel burn-up.

Fig. 1 Reactor building and vertical cross-section of the GFR reactor vessel (IRSN, 2014).

The primary system of the reference GFR concept is relatively simple. The cylindrical vessel with upper and lower spherical parts contains the core and internal cylindrical shell which separates the cold zone (volume in the upper part, downcomer and lower plenum) from the hot zone (upper plenum). Directly interconnected there are one to three Power Conversion Systems with main heat exchangers and blowers and several Decay Heat Removal (DHR) loops. Additionally, the reference design features several gas tanks, connected to the primary circuit. Specific loops for DHR are equipped with heat exchangers and potentially with forced convection devices.

The whole primary system is enclosed in an air tight envelope, a pressure guard containment, which shall limit the consequence of a second safety barriers rupture (of the primary system), but potentially also damage of the first barrier, the fuel clad. The guard containment is designed to provide and maintain a backup pressure in case of large gas leak from the primary system. It shall be a metallic structure, initially filled with e.g. nitrogen slightly above the atmospheric pressure to reduce air ingress capabilities.

Power conversion system utilizes advantages, provided by the high temperature gas in the primary circuit. The choice could be an indirect combined cycle with Helium or Helium-Nitrogen mixture for the intermediate gas circuit. The produced heat will be converted into electricity in the direct or indirect combined cycle, using gas turbines or steam turbine. The cycle efficiency can reach up to around 50%, or even higher if counting with cogeneration or utilization of the excess heat to appropriate technological purposes.

Concerning the objectives of ultimate waste minimization, proliferation resistance and natural resources optimization (zero or positive breeding gain), the major corresponding reactor design options are:

- No fertile blanket and multi-pass recycling of all actinides without separation
- Loading of 1.1% of minor actinides (corresponding to self-recycling)
- A high density fuel with maximization of actinide content
- High core power density of about 100 MW/m³
- Mean overall core Burn-Up: 5% FIMA (fission per initial metal atom) or more, depending on fuel cycle orientation and optimization.

These high level objectives imply various additional secondary specifications such as minimization of the reactivity swings per cycle or minimization of the core pressure drops.

In parallel, the safety architecture was thought to cover the potential defects fitted to this system, due to the following elements:

- Fuel elements that uses refractory materials and withstands very high temperatures
- Gas voiding reactivity effect in the core is not significant, but still positive hence its effect is not negligible
- Decay heat can be removed in any accidental situations (pressurized or not, even in case of large primary break, including an additional single failure or multiple failures), due to different systems of moderate power supply and to a gas tight guard containment
- Natural convection capabilities in DHR can be retained in most of the situations

Nevertheless, several technical fields are only partially covered today, or they are still in need of optimization. One of these critical fields is a full scope and reliable decay heat removal system.

ALLEGRO, as a demonstrator of the GFR technology, represents a necessary step on the path to the deployment of the GFR technology and realization of its high-potential in terms of industrial heat utilization, more efficient use of fuel, and highly competitive costs of both electricity and industrial heat.

Allegro demonstrator development status and R&D major challenges

The ALLEGRO demonstrator is an essential step to establish confidence in the innovative Gas Cooled Fast Reactor (GFR) technology. The development of ALLEGRO is supported by the European Sustainable Nuclear Energy Technology Platform (SNETP). The European Sustainable Nuclear Industrial Initiative (ESNII) as a one pillar of SNETP addresses the need for demonstration of Generation IV Fast Neutron Reactor technologies.

The proposed demonstrator would be the first ever gas cooled fast reactor to be constructed. The ALLEGRO was originally designed by the French Alternative Energies and Atomic Energy Commission (CEA) (Poette, 2009; Poette and Stainby, 2010; Poette and Morin, 2012), among others under EU financed GOFATR project and it is successor of ETDR 50 MW concept (Poette et al., 2007).

The objectives of ALLEGRO are to demonstrate the viability and to qualify specific GFR technologies such as fuel, fuel elements, helium-related technologies and specific safety systems, in particular, the decay heat removal function, together with demonstration that these features can be integrated successfully into a representative system. The ALLEGRO reactor would function not only as a demonstration reactor hosting GFR technological experiments, but also as a test pad of using the high temperature coolant of the reactor in a heat exchanger for generating process heat for industrial applications and a research facility which, thanks to the fast neutron spectrum, makes it attractive for fuel and material development and testing of some special devices or other research works.

The original design of the ALLEGRO consists of two He primary loops, three decay heat removal (DHR) loops integrated in a pressurized cylindrical guard vessel (Figs. 2 and 3). The two secondary gas circuits are connected to gas-air heat exchangers.

The 75 MW_{th} reactor shall be operated with two different cores (Fig. 4). The starting core with UOX or MOX fuel in stainless steel cladding will serve as a driving core for six experimental fuel assemblies containing the advanced carbide (ceramic) fuel. The second core will consist solely of the ceramic fuel and will enable to operate ALLEGRO at the high target temperature. Reflecting the

Fig. 2 ALLEGRO Systems.

Fig. 3 Quasi-isometric cross view of the ALLEGRO nuclear plant.

Fig. 4 ALLEGRO reactor core layout.

demonstrator character of the ALLEGRO, several experimental positions are foreseen. If experimental assemblies are not used, the positions are filled with “steel diluent assemblies” to balance core mixture of steel and helium (Table 1).

Fuel and core design issues

Fuel development to satisfy the needs of a GFR is one of the basic goals of the ALLEGRO project. As the target temperature of the coolant is very high, there is a need to utilize refractory fuel. The ALLEGRO cannot use this type of fuel from the very beginning since this fuel is not developed and cannot be qualified/licensed without irradiations in GFR conditions and without subsequent post irradiation examinations. Therefore, according to previous considerations the first cores will be built up from stainless steel clad fast reactor oxide fuel. Some core positions will be reserved for the development of the refractory fuels through the irradiation of fragments, rods and sub-assemblies. In these positions an elevated helium outlet temperature (800–850 °C) is created by reducing the coolant flow rate.

In relation to the MOX fuel utilization, a serious problem may emerge if ALLEGRO (or any other Generation IV reactor) is built e.g. in eastern Europe EU countries. This is because qualification and use of MOX fuel involves several legal and proliferation issues. In order to overcome these potential difficulties, now it is investigated whether using low enriched UOX pellets can be feasible.

In the existing design of the ALLEGRO core, safety and control rods of identical type are grouped into two independent groups of absorbers. In order to increase the safety of the core design a completely diverse types of absorbers have to be developed which would be activated purely by physical principles in a completely passive manner. It can be for instance system of flow levitated absorbers initiated by changes in coolant flow rate or of curie point latches, initiated by temperature changes.

Table 1 ALLEGRO main design characteristics.

<i>ALLEGRO main design characteristics</i>		
Nominal Power - Thermal	75 MW _{th}	Reduced power is being considered in the range 30–75 MW
Nominal Power - Electrical	0 MW _e	
Fuel / Cladding	UPuC/SiC-SiCf	Reduced power density is being considered in the range 50–75 MW/m ³ Start-up core. Feasibility of low enriched UOX for the start-up core is investigated Long term core
Power density	100 MW/m ³	
Fuel element	MOX/SS cladding	
	UPuC/SiCSiCf cladding	
Number of primary loops	2	
Primary coolant	Helium	
Primary pressure	7 MPa	
Number of secondary loops	2	
Secondary coolant	Water	
Secondary pressure	6.5 MPa	

Decay heat removal issues

Decay heat removal in accident conditions is one of the crucial challenges in design of a GFR reactor because of low thermal inertia of the reactor system and relatively high volumetric power density, one order of magnitude higher in comparison with Very-High-Temperature Reactor. The situation in ALLEGRO is further complicated by the wide use of stainless steel in the driver (start-up) core, because e.g. the 15-15Ti stainless steel claddings start to melt already at ~ 1320 °C. The acceptance criterion (temperature) for fuel rod failure is even lower.

Specific loops for decay heat removal in case of emergency are directly connected to the primary circuit using a cross duct piping, in extension of the pressure vessel, and are equipped with heat exchangers and forced convection devices. In addition, thanks to the low pressure drop of the core design, a passive gas natural circulation can be used in most of the situations.

The original concept of decay heat removal in the 75 MW_{th} ALLEGRO CEA 2009 (~ 100 MWt/m³ power density) was mainly based on active elements in the decay heat removal system, and its malfunction in some cases can easily result in core melting. As the increased use of passive features in safety systems is a pre-requisite of licensing a Generation IV reactor after the Fukushima accident (IRSN, 2014), a new concept of combined active-passive DHR system has to be developed. This is why there are several potential elements of the new DHR system under development.

Allegro research and technology development needs

Coordinated effort is ongoing in EU to restore the ALLEGRO concept and to advance its design. Starting from a reference design studied at CEA prior to 2009, the project explored a new target of nominal power (in the range of 30–75 MW_{th}) and power density (in the range 50–100 MW/m³) compatible with the safety limits and the design requirements. At the same time, the feasibility of a low enriched UOX start-up core as alternative to a standard MOX core is being considered. This start-up core, to be used in the first period of the reactor operation, will include experimental positions dedicated to the refractory fuel development. The development of an acceptable fuel system that meets the target criteria (1000 °C normal operation cladding temperature, no fission product release at 1600 °C cladding temperature during a few hours, and maintaining the core-cooling capability up to 2000 °C clad temperature) is a key viability issue for the GFR system. It is necessary to develop an initial cladding material that meets the core specifications, fabrication capacities and material characterization under full scope of conditions.

The GFR also requires a specific dense fuel element that can withstand very high temperature transients, due to the lack of thermal inertia of the system. UPuC pins fabrication methods, as well as their behavior under irradiation must be studied. Ceramic or refractory metal clad should be selected, developed and qualified. Such a program requires material properties measurements, selection of different materials, their arrangement and their interaction, out-of pile and in-pile tests up to qualification, as well as demonstration tests.

The specific operating conditions of the ALLEGRO oxide fuel pins (i.e. maximum fuel temperature close to 1000 °C, linear pin power below 100 W/cm) are not covered by fuel pin behavior codes. The results of such codes appeared to be very sensitive to fission gas release predictions. In this context, a program of post-irradiation examinations on selected pins of the in PHENIX Sodium Fast Reactor irradiated CPed6106 standard fuel subassembly is suitable for obtaining experimental data on fission gas release for operating conditions similar to those foreseen for the ALLEGRO oxide core fuel pins. Alternatively, a specific irradiation program in other potentially available fast reactors could be envisaged.

In addition to the qualification of the oxide fuel, the reference GFR fuel (i.e. carbide fuel with composite SiC and fiber reinforced SiC clad) development efforts must continue. In particular, it is necessary to develop a ceramic clad that meets the specifications in terms of length, diameter, surface roughness, apparent ductility, level of leak tightness (including the potential need of a metallic

liner on the clad), compatibility with polluted helium, and with the irradiation conditions. The needs include fabrication capacities and material characterization under normal and accidental conditions for fresh and irradiated fuel.

In the area of neutronics, existing calculation tools and nuclear data libraries have to be validated for gas-cooled fast reactor designs. The wide range of validation studies on sodium-cooled fast reactors must be complemented by specific experiments that incorporate the unique aspects of gas-cooled designs: slightly different spectral conditions, innovative materials and various ceramic materials (UC, PuC, SiC, ZrC, Zr₃Si₂). In addition some unique abnormal conditions (e.g. depressurization, steam ingress if relevant, etc.) must be considered.

Given the high temperature environment of the ALLEGRO ceramic core, the design margins considered in terms of material characteristics, as well as in the applied thermal hydraulics correlations must be as low as possible. Therefore, air, followed by helium tests on subassembly mock-ups under representative temperature and pressure conditions are necessary to assess the heat transfer and pressure drop uncertainties for the specific GFR design.

Moreover, large-scale air and helium tests to demonstrate the passive decay heat removal function will be required for the licensing process of ALLEGRO.

Introduction

Historically, the molten salt reactor (MSR) concept, where fissile and fertile materials are dissolved in liquid fluorides/chlorides salt, and fission occurs within the fuel salt, which then flows into an intermediary heat exchanger where the heat is transferred to a secondary liquid-salt coolant, is based on a philosophy that presupposes the use of fuel in a form that permits the continuous management of nuclear-physical, chemical and heat transfer processes in the fuel, as well as the regulation of its nuclides content. This degree of freedom can be used for the optimization of the nuclear energy system and gaining maximal profits from the physical potential of nuclear phenomena, but can also advantageously or disadvantageously affect both the reactor safety and the fuel material attractiveness for nuclear weapon proliferation misuse.

The potential advantages of a fluid-fueled reactor design have been recognized for a long time. Accordingly, the MSR has usual benefits attributed to fluid-fuel systems:

- A high coefficient of thermal expansion, which ensures a large negative temperature reactivity feedback. Because the fuel is liquid, it expands when heated, thus slowing the rate of nuclear reactions and facilitating reactor self-regulation and safety.
- The combination of self-regulation and the ability to dump fuel to a previously prepared storage system, with a geometry designed to render criticality impossible and which also has built-in independent heat removal, was considered the better arrangement from a safety point of view;
- The liquid fuel makes it possible in principle to eliminate a need for reactivity excess required for reactor startup, which can be accomplished by preheating the fuel salt in the subcritical drain tanks up to the working temperature and then filling the primary circuit containing the core;
- The liquid nature of fuel eliminates problems associated with loss of coolant;
- The possibility of continuous fission product removal using physical (helium sparging for noble gases removal) and/or pyrochemical processes. Fuel salt can be processed in an on-line mode or in batches in order to retrieve soluble fission products (lanthanides) and actinides. The actinides are then reintroduced into the fuel circuit.
- No xenon poisoning in thermal spectrum cores.
- Simplifies plutonium and minor actinides handling. Transuranic elements including the actinides could in principle remain in the fluid fuel of the core and be utilized in the neutron flux, either by direct fissioning or transmutation to a fissile element until eventually they all undergo fission. On-line fuel processing offers a safer, more efficient and sustainable nuclear power option.
- The avoidance of the transport and fabrication expenses for new fuel elements.
- Thermal stresses and accumulation of defects in the fuel accompanying a change in power are eliminated;
- The chemical interaction of the fuel salt with the intermediate coolant as well as with the air and water is not accompanied by a release of heat and formation of hydrogen as result of exothermic reactions;
- Radiation damage to the fuel is eliminated, since the radiation resistance of fluoride melts is 10^5 times higher than that of water;
- Heat transfer from the fuel salt to intermediate coolant is outside the neutron field, and the fuel-coolant interface does not affect the neutronic processes in the core;
- Low concentration of the actinide's fluorides in the fuel salt and its large margin relative to the saturation temperature ensure that the thermal reservoir of the primary circuit has a significant capacity and that transient processes proceed without sharp changes of temperature;

As for main challenges it has to be remembered that the fuel salt in MSR fills the whole volume of the primary circuit. It becomes highly active owing to fission products. Sometimes the critics of the MSR say that the use of liquid fuel means the loss of safety barrier (fuel cladding). The number of barriers is not a magic number. What is of real importance is a reliability of barriers not only for liquid, but also gas phase. And if one wants to keep a number of barriers, why shouldn't we to put an additional guard vessel for fluid fuel reactor.

From the 1940s up to now, many molten salt reactor concepts have been proposed all over the world using different fuel (U, Pu, Th, etc.) and salt compositions (fluorides, chlorides, etc.). These projects have tried to find the optimum solution for the fuel salt composition meeting, at the same time, requirements due to: neutronic properties (neutron moderation, breeding ratio, fissile inventory, etc.), reactor core operating temperature (salt melting temperature, radiation stability, transport properties), actinide and fission products solubility in the molten salt to guarantee a homogeneous core composition, materials compatibility and salt chemistry control, and, last but not least, processing and low waste requirements.

This article deals with molten salt reactor concepts where the fuel materials are dissolved in the high temperature molten salt fluoride systems. It is mainly focused on high power rating reactor designs with fast/intermediate neutron spectrum and full

processing of fuel salt. For reactor concepts with a solid fuel and a molten salt fluorides mixture as a primary coolant, which are not addressed here, the reader is referenced to [Fratoni \(2021\)](#).

Historical experience

The fluid-fuel reactor which enjoyed the one of the most extended runs of investigatory life was the molten salt fluoride-based system. This began with an aircraft reactor experiment (ARE) ([Cottrell et al., 1955](#)), which operated successfully in 1954 in a “proof-of-principle” short-term test at a thermal power level of 2.5 MW and at temperatures up to 860 °C. The fuel was a solution of UF₄ in other fluorides, with Inconel-clad beryllium as the moderator. Those who took part in this program realized from the early stages that, potentially, the molten salt system was a candidate for a power reactor, and a team at the US Oak Ridge national Laboratory (ORNL) began work on such a concept in 1957 ([Rosenthal et al., 1970](#)).

Through the 1960s, ORNL investigated large power graphite moderated molten salt reactor designs, both converter reactors and breeder reactors based on the Th-²³³U cycle ([Briggs, 1966](#)). Several designs were proposed using single or two fluid graphite moderated cores. In the two-fluid design, a fuel LiF-BeF₂-UF₄ salt carries the fissile ²³³U, and a separate blanket LiF-BeF₂-ThF₄ salt is used for the fertile thorium. The thorium blanket effectively captures the neutrons that leak from the core region leading to highly efficient neutron use (neutron economy), and a high breeding ratio. ²³³U produced in the blanket, is transferred to the fuel salt by a fluorination process. Fluorination is accomplished by bubbling fluorine gas through the blanket LiF-BeF₂-ThF₄ salt, converting produced UF₄ to volatile UF₆. Gaseous UF₆ is converted back to solid UF₄ before being added as LiF-UF₄ eutectic pellets into the fuel salt. This chemical process is still considered nowadays as a powerful chemical step in the liquid fueled molten salt reactors processing flow sheet. The main advantages of a two-fluid system are a reduced initial fissile inventory, and the simplification of fuel salt clean up from both protactinium (protactinium removal is not necessary as it is diluted in the blanket salt) and soluble rare earth fission products from the fuel salt in absence of thorium. Because thorium and rare earth fission products have similar chemical behavior, the removal of rare earth fission products is greatly simplified without thorium in the core fluid. Rare earth fission products absorb neutrons and reduce the production of new fissile fuel, their concentration in the salt needs thus to be kept low, as they have a large cross section for neutron capture in a thermal neutron spectrum. The two-fluid design offers absolute and incontrovertible advantages, but rises however the problem of the barrier wall (either nickel-based alloy or graphite) between the core and the blanket region, that implies a more complex vessel exposed to fuel redox chemistry and radiation damages.

Vessel complexity and limited graphite lifetime (4 years) in contact with the molten fuel salt steered ORNL toward the development of a simpler single fluid 1000 MWe Molten Salt Breeder Reactor (MSBR) reactor plant design. The proposed MSBR graphite moderated core featured as fuel a LiF-BeF₂-ThF₄-UF₄ (72–16–12–0.4 mol%) salt mixture in the primary circuit, and a NaF-NaBF₄ (8–92 mol%) salt mixture as a coolant in the secondary circuit. An improved but complex processing flowsheet was intensively developed to achieve the difficult separation of thorium from rare earth fission products required for a single fluid design ([Mc Neese et al., 1974](#)).

By the end of 1969 as further development of the concept, a molten salt reactor experiment (MSRE) was built and operated successfully at a thermal power level of 7.3 MW and temperatures up to 700 °C with Li, Be, Zr, U, Pu/F fuel salt ([Haubenreich and Engel, 1970](#)). In MSRE primary Li, Be, Zr, U, Pu/F and secondary Li, Be/F circuits were made of the Hastelloy N alloy (base Ni-16Mo-7Cr-5Fe). The MSRE was a very successful experiment, in that it answered many questions and posed a few new ones. Arguably, the most important result was the conclusion that such a concept had the potential to become a practical reactor:

- Keeping salt in the molten state was not difficult.
- Moving salt among tanks was routine.
- No salt leaks during operation.
- Adding enriching salt during operation was uneventful (²³⁵U and ²³³U added as LiF-UF₄ eutectic; plutonium added as PuF₃).
- Static nuclear properties were accurately predicted.
- Excellent dynamic stability with both ²³⁵U and ²³³U as predicted.
- Reactivity change with time as expected (no evidence of uranium loss or deposition).
- Heat transfer and hydraulic performance as predicted.
- No pump maintenance required.
- Stripping of noble gas fission products was effective.
- Good gaseous UF₆ recovery.
- Effective oxide removal from fuel salt
- Substantial corrosion of reactor vessel, as expected.

MSRE ran for long periods of time. It is of interest that it operated initially on ²³⁵U, then on ²³³U, and finally on plutonium. There has always been some controversy as to how a ²³³U-Th system should be started initially, and the plutonium experiment was intended to demonstrate the feasibility of operating with plutonium as the initial fissile material. It is of interest that substantial dismantling of MSRE was achieved very satisfactorily, results being obtained on fission-product deposition and take-up. Although this was only on small-scale plant, the experience from an active-handling point of view was encouraging. Following MSRE

shutdown, the Oak Ridge program concentrated on a number of important items requiring development if the system was to be of commercial interest. Materials problems had been encountered (Haubenreich and Engel, 1970):

1. Hastelloy N was susceptible to damage from helium formation in a neutron radiation field ("radiation hardening"). Later it was found that modified alloys that had fine carbide precipitates within grains would hold the helium and restrain its migration to the grain boundaries.
2. The circuit material specially developed for the system by ORNL (Hastelloy N) was deteriorating in its properties as a result of intergranular attack caused, it was believed, by the fission product tellurium. Later work showed that this tellurium attack could be controlled by keeping the fuel on the reducing side. This is done by adjustment of the chemistry so that about 2% of uranium is in the form of UF_3 as opposed to UF_4 .
3. Tritium formed from the primary salt by neutron reactions mainly with lithium was presenting difficulties as it diffused (as does hydrogen) through the primary and secondary heat exchanger tube walls and led to radioactivity in the steam circuit. After considerable development work it was found that the intermediate salt coolant NaF-NaBF_4 , would capture the tritium that could be then removed and isolated in the gas purge system.
4. In the graphite, xenon and iodine were being taken up to the detriment of the nuclear performance—a non-wetting graphite was needed.
5. In addition, further work in the processing field was clearly identified.

Despite the success of the MSRE reactor and the large research and development efforts including natural and forced convection molten salt loop tests demonstrating many aspects of the reactor technology, the molten salt reactor program at ORNL was closed down in the early 1970s in favor of the liquid metal cooled fast-breeder reactor (Rosenthal et al., 1970). Oak Ridge did continue a modest program until the early 1980s and proposed another molten salt reactor design, the denatured molten salt reactor (DMSR) developed in the 1970s to address proliferation concerns. In the DMSR concept, full fuel salt processing was not performed (other than krypton and xenon gas removal), enriched uranium (19.75%) was used at start-up and as feed material to maintain criticality, and ^{238}U was added as needed to maintain denatured state (Engel et al., 1980). The simplified DMSR converter design with a low power density core allowing a full 30-year graphite lifetime was called the "30 Year Once Through Design". During this period, more countries, including China, France, Japan and the Russian Federation, also placed some efforts in the molten salt reactor concept developments.

Developments within the Generation IV International Forum (GIF) collaboration framework

The new interest in molten salt reactors is a consequence of changing goals and changing technologies. The today family of MSRs (Serp et al., 2014), can be split into several categories depending on the choice of the fissile and fertile materials, the neutronic spectrum, the salt type, the power level, the fuel salt processing mode (limited or full), etc. Although the design of all these reactors will be different, some key safety features will be quite similar, for example the approach for defining the barriers, the definition of the severe accidents, etc. However, some features can differ in particular between graphite moderated and non-graphite moderated cores.

There is a renewed interest in breeder reactors and reactors for the utilization of transuranic elements (TRU) from used fuel. For the latter option, molten salt reactors have the unique advantage that there is no fuel fabrication step—an extremely complex task for fuel elements with higher actinides. Several national or international molten salt reactor concepts were conceived and new research programs were recently launched worldwide (see Table 1).

The MSR developers are in some cases directly supported by national government funded programs. In many cases, however, the developments are being primarily supported by private capital. The different development organizations have differing development strategies. Some are constructing non-nuclear demonstration facilities that are intended to support test reactor development. Others are preparing for performing component and system tests to support first-of-a-kind power reactor deployment. The private companies view each other as competitors, often have patents (or have filed patent applications) on key design features, and are protective of their technology and design information. This section discusses relevant molten salt reactor features being investigated within the GIF collaboration framework.

Within the GIF collaboration framework, a memorandum of understanding between Australia, Canada, France, Euratom, the Russian Federation, Switzerland and United States (with China, Japan and the Republic of Korea as observers) is providing a flexible structure for R&D cooperation on molten salt reactor concepts (Serp et al., 2014).

The common objective of molten salt reactor projects in different GIF countries is to propose a conceptual design with the best system configuration—resulting from physical, chemical and material studies—for the reactor core, the fuel salt processing unit and wastes conditioning. The mastering of molten salt reactor technically challenging technology is requiring concerted, long-term international R&D efforts, specifically:

- Additional studies of the salt physical, chemical and thermodynamic properties,
- System design and safety analyses, including development of advanced coupled neutronic and thermal hydraulic simulation models,

Table 1 List of the different MSR systems (Dolan, 2017).

Name	Developer	Power (MWt)	Fuel/carrier/moderator
Thermal Spectrum MSRs			
Thorium Molten Salt Reactor–Liquid Fuel (TMSR-LF)	SINAP, China	395	ThF ₄ - ²³³ UF ₄ /LiF-BeF ₂ /graphite
Integral Molten Salt Reactor (IMSR)	Terrestrial Energy, Canada and USA	400	UF ₄ /fluorides/graphite
ThorCon Reactor	ThorCon International, Singapore	557 × 2	ThF ₄ - ²³³⁻²³⁵ UF ₄ /NaF-BeF ₂ /graphite
Liquid-Fluoride Thorium Reactor (LFTR)	Flibe Energy, USA	600	ThF ₄ - ²³³ UF ₄ /LiF-BeF ₂ /graphite
FUJI-U3	Japan	450	ThF ₄ - ²³³ UF ₄ /LiF-BeF ₂ /graphite
Advanced Molten Salt Break-Even Inherently-Safe Dual-Mission Experimental and Test Reactor (AMBIDEXTER)	Ajou University, Republic of Korea	250	²³³ UF ₄ -ThF ₄ /LiF-BeF ₂
Transatomic Power MSR (TAP)	Transatomic Power, USA	1250	UF ₄ /FLiNaK/SiC clad ZrH _{1.6}
Compact Used Fuel Burner (CUBE)	Seaborg Technologies, Denmark	250	SNF/fluorides/graphite
Process Heat Reactor	Thorenco, USA	50	UF ₄ /NaF-BeF ₂ /Be rods
Stable Salt Thermal Reactor (SSR-U)	Moltex Energy, UK	300–2500	UF ₄ /fluorides/graphite
Fast/Epithermal Spectrum MSRs			
Molten Salt Fast Reactor (MSFR)	SAMOFAR, France–EU–Switzerland	3000	ThF ₄ -UF ₄ /LiF-
Molten Salt Actinide Recycler and Transformer (MOSART)	Kurchatov Institute, Russia	2400	TRUF ₃ or ThF ₄ -UF ₄ /LiF-BeF ₂ or NaF- ⁷ LiF-BeF ₂
U-Pu Fast Molten Salt Reactor (U-Pu FMSR)	VNIINM, Russia	3200	UF ₄ -PuF ₃ /LiF-NaF-KF
Indian Molten Salt Breeder Reactor (IMSB)	BARC, India	1900	ThF ₄ -UF ₄ /LiF-
Stable Salt Fast Reactor (SSR-W)	Moltex Energy, UK	750–2500	PuF ₃ /fluorides
TerraPower Molten Chloride Fast Reactor (MCFR)	TerraPower (USA)	30	U-Pu/chlorides
Molten Chloride Salt Fast Reactor (MCSFR)	Elysium Industries (USA and Canada)	100–5000	U-Pu/chlorides
Dual Fluid Reactor (DFR)	Dual Fluid Reactor, Germany	3000	U-Pu/chlorides

- Development of advanced materials, including studies of their compatibility with molten salts and behavior under high neutron fluxes at high temperature conditions,
- Mastering of corrosion and tritium release prevention technologies, based on proper molten salt Redox control,
- Development of efficient techniques of gaseous fission products extraction from the fuel salt by helium bubbling,
- Fuel salt processing flowsheet, including reductive extraction tests (actinide-lanthanide separation),
- Development of a safety, safeguards, security and proliferation resistance approaches dedicated to liquid fuelled reactors.

Thermal spectrum cores

As can be seen from Table 1, Canada, Japan, Singapore and South Korea are paying attention to the development of the small and medium power liquid fuel units with thermal-neutron spectrum graphite moderated cores and limited fuel salt processing. In China, the Thorium Molten Salt Reactor (TMSR) Program was initiated by the Chinese Academy of Sciences (CAS) at Shanghai Institute of Applied Physics (SINAP) in 2011, which involves a closed U-Th fuel cycle for MSR (Serp et al., 2014). The new candidate site for the 2 MWt TMSR-LF1 test reactor was selected in 2017. It will be located in Wuwei, Gansu Province, about 2000 Km from Shanghai.

The thermal spectrum MSR approach involves moderator material, with the most commonly proposed being graphite, as it has been shown to be directly compatible with fluoride fuel salts. Several other moderators have been suggested such as metal hydrides (or deuterides), Be or BeO, and even water, heavy water and molten sodium hydroxide. Each non-graphite alternative has specific challenges and all of them do require cladding materials to be validated for use in contact with fuel salts in a high neutron flux environment. All thermal spectrum MSR variants offer benefits in terms of the safety case development including large thermal inertia, longer neutron lifetimes and practically absence of out of core criticality issues due to the low fissile enrichment levels in the fuel salts.

Thermal spectrum MSR variants can suit almost all fuel cycles. Traditional thermal-neutron spectrum graphite moderated MSRs require full and relatively rapid processing of the molten salt if they are to be breeder reactors (Dolan, 2017). For the thorium-²³³U breeder cycle there is the advantage of very low starting fissile inventory to compensate for lower breeding ratios compared to fast spectrum variants. The thermal spectrum opens the possibility of simplified converter options, removing the need for fuel processing by employing low enriched uranium (LEU), on its own or in combination with thorium. In fact, the use of commercially available standard assay uranium enrichment (<5%) is possible to further simplify development time-lines. Converter designs also allow consideration of carrier salts that are free from the need for enriched lithium 7 and/or beryllium (and their tritium production) as neutron economy is of lower importance for converters. The thermal spectrum approach has a larger historic development foundation and ability to significantly lower neutron flux reaching reactor vessel material compared to fast spectrum MSR.

ThorCon

ThorCon is a straightforward scale-up of the successful US MSRE at Oak Ridge National Laboratory. ThorCon uses only commercially available components and materials, such as SS316 steel, but avoiding unobtainable lithium-7 for molten salt. Fuel salt with dissolved thorium and uranium (enriched to 19.7%) fluorides is similarly removed and replaced, on an 8-year cycle (Dolan, 2017). ThorCon is divided into 250 MWe power modules or PMODs. Each module contains two replaceable reactors in sealed Cans. The Cans sit in silos. At any one time, just one of the Cans of each module is producing power. The other Can is in cooldown mode.

The Can contains the reactor, called the Pot, a primary loop heat exchanger (PHX), and a primary loop pump (PLP). The pump takes fuel salt from the Pot at 704 °C, and pushes the fuel salt over to the PHX at a rate of just under 3000 kg/second. Flowing downward through the PHX, the fuel salt transfers heat to a secondary salt, and is cooled to 565 °C in the process. The fuel salt then flows over to the bottom of the Pot, and rises through the reactor core, which is mostly filled with graphite blocks.

The Pot pressure is 3 bar gage. The outlet temperature of 704 °C results in an overall plant efficiency of 46%. The Can is a cylinder 11.6 m high and 7.3 m in diameter. It weighs about 400 tons. The Can has only one major moving part, the primary loop pump.

Every 4 years the Can that has been cooling is removed and replaced with a new Can. The fuel salt is transferred to the new Can, and the Can that has been operating goes into cool down mode. Every 4 years the entire primary loop is changed out, returned to a centralized recycling facility, decontaminated, disassembled, inspected, and refurbished. Incipient problems are caught before they can turn into casualties. Upgrades can be introduced without significantly disrupting power generation.

Each ThorCon plant is based on one or more hulls, each containing two 250 MWe power modules, a 500 MW super-critical turbogenerator, gas insulated switchgear (GIS), a decay heat pond, and auxiliaries. The fission island is at the forward end of the hull. Aft of the fission island is the steam generating cell (SGC). Aft of the SGC is the turbine hall, which contains the turbogenerator, exciter, condensers, feed heaters, pumps, and condensate treatment.

The complete ThorCon is manufactured in 150–500-t blocks in a shipyard, assembled, then towed to the site. This produces order of magnitude improvements in productivity, quality control, and build time. A single large reactor yard can turn out 20 GW of ThorCon power plants per year. ThorCon is a system for building power plants. Shipyards can rapidly fabricate 500 MW power plants on hulls to be towed to near-shore sites. Claim is made that prototype could begin testing in 4 years.

ThorCon has been working with the Indonesian government to add reliable electric power to the grid. In 2019 the Ministry of Energy successfully completed a study of the safety, economics, and grid impact of the 500 MWe prototype ThorConIsle. Phase 1 is to build and test it with step by step commissioning, ending in a type license for future power plants. Phase 2 is shipyard production of ThorCon plants to provide an additional 3 GW of cheap, reliable electric power.

IMSR

The integral molten salt reactor is so called because it integrates into a compact, sealed and replaceable nuclear reactor unit, called the IMSR Core-unit (LeBlanc, 2010; Dolan, 2017). The Core-unit comes in a single size designed to deliver 400 MW of thermal heat which can be used for multiple applications. If used to generate electricity then the notional capacity is 190 MW electrical. The unit include all the primary components of the nuclear reactor that operate on the liquid molten fluoride salt fuel: moderator, primary heat exchangers, pumps and shutdown rods. The Core-unit forms the heart of the IMSR system. In the Core-unit, the fuel salt is circulated between the graphite core and heat exchangers. The Core-unit itself is placed inside a surrounding vessel called the guard vessel. The entire Core-unit module can be lifted out for replacement. The guard vessel that surrounds the Core-unit acts as a [containment vessel](#). In turn, a shielded silo surrounds the guard vessel.

The IMSR is designed to have all the safety features associated with the MSR family including low pressure operation (the reactor and primary coolant is operated near normal atmospheric pressure), the inability to lose primary coolant (the fuel is the coolant), the inability to suffer a meltdown accident (the fuel operates in an already molten state) and the robust chemical binding of the fission products within the primary coolant salt (reduced pathway for accidental release of fission products).

The design uses standard assay [low-enriched uranium](#) fuel, with less than 5% U²³⁵ with a simple converter [fuel cycle](#) objective (as do most operating power reactors today). The IMSR is a [thermal-neutron reactor](#) moderated by vertical [graphite](#) tubular elements. The molten salt fuel-coolant mixture flows upward through these tubular elements where it goes critical. After heating up in this moderated core the liquid fuel flows upward through a central common chimney and is then pulled downward by pumps through heat exchangers positioned inside the reactor vessel. The liquid fuel then flows down the outer edge of the reactor core to repeat the cycle. All the primary components, heat exchangers, pumps etc. are positioned inside the reactor vessel. The reactor's integrated architecture avoids the use of external piping for the fuel that could leak or break.

The piping external to the reactor vessel contain two additional salt loops in series: a secondary, nonradioactive coolant salt, followed by another (third) coolant salt. These salt loops act as additional barriers to any radionuclides and improve the system's heat capacity. It also allows easier integration with the heat sink end of the plant; either process heat or power applications using standard industrial grade [steam turbine](#) plants are envisioned by terrestrial energy.

The IMSR Core-unit is designed to be completely replaced after a 7-year period of operation. This ensures that a sufficient operational lifetime of materials used in the IMSR reactor core can be achieved. During operation, small fresh fuel/salt batches are periodically added to the reactor system. This online refueling process does not require the mechanical refueling machinery required for solid fuel reactor systems.

Fast spectrum and intermediate cores

R&D within the GIF collaboration framework is mainly focused on MSR options with homogeneous cores without graphite moderator. Fast MSRs have strongly negative reactivity coefficients, a unique safety characteristic not found in solid-fuel fast reactors (Allibert et al., 2016). Compared with solid-fuelled reactors, those systems have lower fissile inventories, no radiation damage constraints on attainable fuel burnup, reduced radiation damages to materials since no solid materials are located in the center of the core, no used nuclear fuel, no requirement to fabricate and handle solid fuel, and a homogeneous isotopic composition of fuel in the reactor.

A molten chloride fast spectrum reactor (MCFR) concept based on U/Pu fuel cycle (Krepel et al., 2021) has been under development by TerraPower Inc. for the past 5 years. The MCFR is intended to have a very hard neutron spectrum to avoid requiring any fissile material input after its initial core load or separation of fissile materials from the remainder of the fuel salt.

The fast neutron spectrum MSRs loaded with fluoride fuel salt open promising possibilities to exploit the ^{232}Th - ^{233}U cycle and can also contribute, in the transmuter mode, to significantly diminishing the radiotoxic inventory from current-reactor used fuel in particular by lowering the mass of TRUs. Developments in Russia (Ignatiev et al., 2014) on the 2400 MWt molten salt actinide recycling and transmuter (MOSART) and in France (Heuer et al., 2014) on the 3000 MWt thorium molten salt reactor (MSFR) address the concept of large power units. The first concept aims to be used as an efficient burner of TRU waste from used LWR fuel without uranium and thorium support. The fast-spectrum MSRs have a higher breeding ratio that enables the reactor to be a breeder reactor with longer cycle times to remove soluble fission products. When comparing with the reference 2250 MWt MSBR design, for which a 4 m³/day reprocessing rate was mandatory to insure a sufficient breeding ratio, the processing rate can be reduced to 0.04 m³/day in the MSFR concept (Doligez et al., 2014). Pyrochemical salt processing in MCFR, MOSART and MSFR designs is mandatory to avoid the accumulation in the fuel salt of large quantities of lanthanides and zirconium that could be detrimental to several physical-chemical properties, such as actinide trifluorides solubility. The availability of a high neutron flux and the lack of structural materials in the liquid homogeneous core, lead to the optimization of the neutron balance, as well as to increased flexibility allowing fuel salt composition changes without core modification and/or reactor shutdown. The plutonium and minor actinides (MA) burning rate is directly proportional to the core power density.

MOSART

A promising single fluid configuration for the 2400 MWt MOSART is the homogeneous cylindrical core 3.6 m high and 3.4 m in diameter (See Fig. 1, right side) filled with 100% of 73LiF-27BeF₂ (mol%) salt mixture (Ignatiev et al., 2014). It is feasible to design a critical homogeneous core fuelled only with TRU trifluorides from UOX or MOX LWR used fuel and ensuring that the TRU equilibrium concentration is kept below the solubility limit (~ 3 mol%) in trifluorides at 650 °C, that is, the minimum fuel salt temperature in the primary circuit. The effective neutron flux in the fuel is close to $1 \times 10^{15} \text{ n cm}^{-2} \text{ second}^{-1}$ (Ignatiev et al., 2014). The 2400 MWt MOSART core that was initially loaded with TRU fluorides derived from the used fuel of a LWR having 10–15% MA/(plutonium + MA) ratio is able to accommodate TRU fluorides make-up with up to 33% MA/(plutonium + MA) ratio, without any core modification. The equilibrium TRU loading in primary circuit was calculated to be in the range of 3.6–20.0 t, depending on the MA/(plutonium + MA) ratio in the core make-up. The studies showed that the 2400 MWt MOSART can transmute up to 250 kg of minor actinides and about 500 kg of plutonium per year (in the case of make-up loadings having 33% MA/(plutonium + MA) ratio).

The structural material selected for the MOSART fluoride-salt container is the special Ni-Mo HN80MTY alloy type with a low concentration of Cr alloyed by 1% of Al. The composition of the alloy is optimized for corrosion resistance (both in a low oxygen gas atmosphere and in molten salt fluorides), irradiation resistance, and high temperature mechanical properties (Ignatiev and Surenkov, 2017).

Interior Ni-base reflectors/shielding are employed to reduce the radiation damage to the reactor vessel (see Fig. 1, right). Fuel salt chemistry control is employed to substantially limit oxidizing the container alloy constituents. For those systems that include graphite, the salt is maintained in a redox window oxidizing enough to prevent damage to the graphite while reducing enough to prevent alloy oxidative corrosion. The systems without graphite can maintain the salt in a more reducing condition.

The radiation resistance of reflectors/shielding material determines the upper limit for the fuel salt power density in the MOSART design. While the damage caused by fast neutrons is critical for graphite, for high-nickel alloys the reduction in plasticity at a temperature above 500 °C, associated with the formation of helium, due to neutron absorption by Ni, along the grain boundaries, is the most important process, caused by both fast and thermal neutrons. To obtain an acceptable service life for reflectors (> 5 years), the core power density should not exceed 130–150 W/cm³. Otherwise, frequent stops to replace the reflector will result in a reduction in the reactor load factor and an unjustified increase in operating costs. In addition, with this limitation for the core power density, there is no problem of heat removal from the fuel circuit. In this case the service life for the reactor vessel, made of the HN80MTY alloy, will be about 50 years. For the 2400 MWt MOSART, taking into account the adopted limits, the primary circuit will contain 50 m³ of fuel salt, of which only half is in the core.

For MOSART, the proposed fuel salt processing to remove fission products (see Table 2), and the required fuel maintenance operations include (1) continuous removal (by the sparging and stripping section of the reactor) of the fission products krypton and xenon, (2) addition of TRUs to replace those lost by burnup, (3) recycling of all actinides, (4) removal of soluble fission

products (principally rare earths), (5) removal of inadvertent oxide contaminants from the fuel, if any, and (6) removal of a portion of the insoluble noble and semi-noble fission products.

For multiple TRUs recycling, since plutonium and minor actinides must be removed from the fuel solvent before yttrium and rare earth fission products, the MOSART must include a system that provides removal of TRUs from the fuel salt and their reintroduction to the purified solvent. This plutonium reintroduction circuit has the advantage of also returning americium and curium to the reactor fuel (low separation coefficients within TRU group). Since the higher actinides would always accompany the plutonium, this operation would never produce a “clean” fissile material that would be attractive for diversion. Adoption of the molten Li, Be/F salt mixture, due to the high separation coefficients between actinides and lanthanides, thus providing effective removal of soluble fission products based on the reductive extraction. This, in turn, allows (in comparison with solid fuel reactors) to substantially reduce the time, during which actinides reside in the external fuel cycle, as well as the losses in waste streams in the case of multiple recycling.

The flexibility of the single fluid MOSART concept fuel cycle is allowing its operation in self-sustainable mode using different loadings and make-up. For example, the single fluid 2400 MWt Li, Be/F MOSART core containing an initial loading of 2 mol% of ThF_4 and 1.2 mol% of TRUF_3 , adopting a LnF_3 removal cycle of 300 EFPD after 12 years of a slow increase of its thorium content in the solvent, can operate as a self-sustainable system without any TRUF_3 make-up, relying only on thorium support. The maximum concentration of TRUF_3 during this transition does not exceed 1.7 mol%. At equilibrium the molar fraction of ThF_4 fertile material in the fuel salt is nearly 6%, and it is enough to support the system with a conversion rate equal to one for a period of 50 years reactor lifetime.

MSFR

The reference MSFR supported by the European Union is a 3000 MWt reactor with a total fuel salt volume of 18 m^3 , half of the salt (9 m^3) located in the core and half in the external circuits: salt collectors, salt-bubble separators, fuel heat exchangers, pumps, salt injectors and pipes (Heuer et al., 2014). The fuel salt runs through the total cycle in 3–4 seconds. The fuel salt is composed of lithium fluoride and thorium fluoride, and the proportion of heavy nuclei is fixed at 22.5 mol%. The preliminary design of the primary circuit of the MSFR is a single compact cylinder 2.25 m high $\times$ 2.25 m diameter (see Fig. 1, left), where the nuclear reactions occur within the liquid fluoride fuel salt acting also as the coolant. The operating core temperatures for fuel salt chosen are 650°C (inlet temperature) and 750°C (outlet temperature). The lower limit is set by the salt's melting point (565°C), while the upper limit is imposed by the Ni base structural materials performance (limit around 800°C). The fuel salt flows in the central part of the core freely from the bottom to the top without any solid moderator. The return path of the salt is divided into 16 sets of pumps and heat exchangers located around the core. Bubbles are injected in the fuel salt circulation after the exchangers and separated from the liquid at the core outlet. As in MOSART the lower neutron reflector is connected to a drain system enabling the reactor core to be drained for planned shut downs or in case of incidents that lead to a temperature increase in the core. Thus, the entire fuel inventory

Fig. 1 MSFR (left) and MOSART (right) concepts.

Table 2 Summary time-lines for fission product removal and actinides recycling in MOSART (Ignatiev et al., 2014).

Element	Time
Kr, Xe	50 seconds
Zn, Ga, Ge, As, Se, Nb, Mo, Ru, Rh, Pd, Ag, Tc, Cd, In, Sn, Sb, Te	2–4 hours
Zr	1–3 years
Ni, Fe, Cr	1–3 years
Pu, Am, Cm, Np, U	1–3 years
Y, La, Ce, Pr, Nd, Pm, Gd, Tb, Dy, Ho, Er	1–3 years
Sm, Eu	1–3 years
Sr, Ba, Rb, Cs	5–10 years
Li, Be, Th	50 years

can be passively drained by gravity into subcritical, passively cooled tanks. The MSFR can be started either directly with ^{233}U as fissile matter or with a mix of enriched uranium (13%), plutonium and minor actinides from PWRs spent fuel. MSFR configurations corresponding to various starting modes of the reactor are all characterized by excellent safety reactivity coefficients and have the same very good deployment capabilities. In the MSFR, the liquid fuel processing is an integral part of the reactor where a small fraction of the molten salt (40 L/day) is set aside to be processed for fission product removal and then returned to the reactor. Actinides and soluble fission products that are strongly bound to the salt, can be separated by pyro-chemical techniques. The most effective technique to achieve uranium removal seems to be fluorination as UF_6 . The fast neutron spectrum relaxes the requirements for soluble fission product removal times by reductive extraction process up to 1 year.

The common objective of the MOSART and MSFR projects is to develop a conceptual design for intermediate/fast-spectrum MSRs with an effective system configuration—resulting from physical, chemical and material studies—for the reactor core, the reprocessing unit and waste conditioning. The conceptual design activities are intended to increase the confidence that fast-spectrum MSR systems can satisfy the goals of GIF reactors in terms of sustainability (Th breeder), non-proliferation (integrated fuel cycle, multi-recycling of actinides), resource savings (closed Th/U fuel cycle, no uranium enrichment), safety (no reactivity reserve, strongly negative feedback coefficient) and waste management (actinide burner). No show stoppers have been identified but almost all the technology remains to be tested and a safety approach dedicated to this type of reactors has to be developed to assess the potential advantages and to prove the viability of such innovative of fast-spectrum molten salt systems.

Open technical issues and future R&D priorities

Specific scientific and technological challenges remain for the development of liquid fueled MSRs and the safety approach has yet to be established (Serp et al., 2014). Liquid fueled MSR viability assessment should address the essential R&D issues discussed below in this section.

Salt and container material

Experimental investigations of physical-chemical properties of fuel salts are carried out to elucidate the influence of the salt composition on thermal and physical properties (melting temperature, solubility of actinides and vapor pressure). Experimental results, received in the Russian Federation and Euratom laboratories on key physical and chemical properties of MOSART and MSFR fuel salts, which determine main core parameters (e.g., inlet/outlet temperatures, critical loadings and temperature reactivity coefficient of the fuel salt, etc.) are described in detail elsewhere (Ignatiev et al., 2016). These data are now used in multi-physics numerical codes (neutronics and thermo-hydraulics) for the simulations of the fuel salt heat and flow distribution in the reactor cavity (reactor reactivity, fuel irradiation, reactivity feedback coefficients, reactor core wall temperature, etc.).

A large body of literature exists on the corrosion of metallic alloys by molten salt fluorides. Much of this work was done in the past at ORNL (Mc Neese et al., 1974) and later at Kurchatov Institute (Novikov et al., 1984). It involved both thermal and forced convection loops. Uniform corrosion is in the form of bare alloy dissolution driven by the oxidants in the salt. The thermal gradient driven corrosion is inevitable in the MSR circuits. Thus, the corrosion rate at hot sections must be minimized to avoid the clogging problems at cold sections for heat exchangers. The major impurities that must be removed to prevent severe corrosion of the container metal are moisture/oxide contaminants. During the US MSR program, considerable effort was devoted to salt purification by HF/H_2 sparging of the molten salt, which is described in numerous ORNL reports (Mc Neese et al., 1974). A great deal of effort has still to be devoted to develop analytical and purification methods able to:

- Identify the oxygen-containing species (oxide type, hydroxyl, etc.),
- Purify the molten salt mixture,
- Determine accurately the oxygen content in salt melts.

The structural materials retained for the MSR container are special Ni-Mo alloys with a low concentration of Cr down to 6–7 mass%. The composition of the alloy was optimized by ORNL researchers for corrosion resistance (both in a low oxygen gas atmosphere and in molten fluorides), irradiation resistance and high temperature mechanical properties. Less severe corrosion attack ($< 10 \mu\text{m}/\text{year}$) was seen for the Hastelloy N in contact with the MSRE fuel $\text{LiF-BeF}_2\text{-ZrF}_4\text{-UF}_4$ salt at temperatures up to 700°C for 3 years (26,000 hours). The most surprising observation was the almost complete absence of corrosion for Hastelloy N during the 3-year period to the MSRE coolant LiF-BeF_2 salt.

Hastelloy N, is not currently approved by ASME code as a material for high-temperature nuclear power plants. Thus, a materials qualification effort would be required for use of Hastelloy N in any part of the containment boundary or to perform any other safety function. Developing a safety case for limited term Hastelloy N use at temperatures less than 700°C may be possible based upon existing data from the earlier MSR program and/or limited term supplemental qualification testing. The maximum allowable stress for Hastelloy N decreases rapidly above 600°C , becoming too low for practical use above 700°C . Compared to the leading candidate materials that are usually considered for high-temperature nuclear reactor construction, Hastelloy N has significantly lower high-temperature strength. However, developing and qualifying improved performance alloys for longer term high stress applications will require substantial investment over a number of years. Kurchatov Institute in the Russian Federation and US ORNL has continued the development of successor alloys to Hastelloy N (Ignatiev and Surenkov, 2017). Samples of the new alloys (e.g., Russian HN80MTY alloy) show promise for application in high stress applications at higher temperatures along with good fluoride salt corrosion resistance. As a first step, early phase, long-term advanced salt-compatible alloy property measurements will need to be performed. Thus, improved alloys can be developed and made available for commercial MSR deployments while a limited-term safety case for use of Hastelloy N at test reactors can be developed in parallel.

Material integrity is directly linked to the instrumentation and control of liquid salt because the corrosion of the structural materials by the molten salt strongly depends on the redox potential of the salt. It has been demonstrated that the salt redox potential is a key parameter in the corrosion phenomena of structural materials of MSRs. The chemical corrosion can be controlled by a redox buffer, which controls the potential of the fuel salt. The redox buffer considered for MSR is the redox system U(IV)/U(III) . This potential has to be measured on line in the reactor core because the potential increases with operation time due to the fission reactions. Addition of a reducing agent leads to a decrease of the fuel salt potential.

From 1965 to 1969, the successful operation of the MSRE proved that the fission of $^{235}\text{UF}_4$ as well as of $^{233}\text{UF}_4$ made the fuel salt moderately oxidizing and proved the absence of metallic uranium deposition or uranium carbide formation incidence due to successive fissioning. The U(IV)/U(III) ratio could be maintained within the projected range by periodic dissolution of beryllium metal bar suspended in the pump bowl. A 10 g Be metal bar equivalent to 300 g of U(III) and could compensate fissioning effect for 10,000 full power days operation of the 7.5 MW MSRE. During the post MSRE work, it was found that the significant inter-granular cracks in Hastelloy N due to presence of fission product tellurium could be suppressed by adjusting the U(IV)/U(III) ratio no higher than 70.

In 1968, before the MSRE was switched to ^{233}U operation, ORNL claimed that no significant differences are believed to exist in the yields or chemistry of the principal species of fission products which would result from incorporation of PuF_3 in MSR fuels. Indeed, there were fission yield data for thermal fission of ^{235}U in a nuclear engineering handbook at that period, but no data were available for ^{239}Pu fission.

The feasibility of using PuF_3 in startup operation of an MSR did not therefore appear to require separate research program relative to fission products from plutonium. ORNL described further that with UF_4 as the fissile solute, a slight excess of fluoride ions developed. Use of a trifluoride solute, however, should result in a cation excess, and should cause the fuel solution to generate a mild reducing potential. This last sentence was undisputable; however, there might be some prejudice even if he had described “trifluoride solute” but not “plutonium trifluoride.”

The recommendation by ORNL at that time was; redox potential control of the salt loop was achieved by a combination of redox adjustment and redox buffering. A redox buffer, such as the U(III)/U(IV) couple used during MSRE, is a sink for absorbing the chemical effects of fission in safe manner. For MSR systems that did not contain uranium it was proposed that the Ce(III)/Ce(IV) couple be used as a buffer. The level of buffer need not be any greater than that of the uranium used during the last phase of MSRE operation (0.13 mol%), and can probably be much less. If in-line, side stream, or semi-batch adjustment of redox state of the salt was accomplished (either electrochemically or by hydrofluorination) then it might not be necessary to add a redox buffering agent at all. Hydrofluorination of the salt to set the redox state of the salt has been well established and the only barrier to its implementation was the natural desire to exclude HF from the primary off-gas systems. Because of this bias, it was probably more practical to consider a side stream or semi-batch hydrofluorination operation.

The adoption of fast spectrum MSR designs and the possible application of MSR as industrial heat sources have introduced new challenges such as higher salt operating temperatures (up to 750°C), metallic barriers and reflectors able to function in a strong neutron flux. The compatibility of salts with structural materials for fuel and coolant circuits, as well as fuel processing material development needs thus to be addressed.

Special attention will have to be paid to the measure and control of the U(IV)/U(III) ratio in order to reach the desired corrosion resistance of Ni based alloys (Engel et al., 1980). The instrumentation and control of liquid salt must be developed with in-situ measurements at a lab-scale in order to:

- Measure and control the redox potential of the salt and to limit the corrosion.
- Measure the composition of the salt containing fissile and fertile elements.

In MSR Te fission product diffuses to container material preferentially along the grain boundaries and causes IGC by the formation of brittle metallic tellurides on grain boundaries. The formation of these telluride compounds is probably by the reactions of Te with Ni and Cr (Ignatiev and Surenkov, 2017). There exist two options to reduce the tellurium induced IGC. The first option is to minimize the preferential formation sites (e.g., intergranular carbides) for tellurides by alloy modifications with Nb or Al. The other option is to reduce the Te to its negative oxidation states in the salt by controlling the redox condition.

To improve the resistance of Ni-based alloys against irradiation embrittlement, additions of alloying elements to form finely dispersed carbides within the grains have been found to be effective (Ignatiev and Surenkov, 2017).

Experiments have shown that the radiation damage accelerates the corrosion of Hastelloy N exposed to molten fluoride salts. The resistance of Hastelloy N to damages caused by simultaneous thermal neutron radiation and molten salt corrosion seems adequate based on MSRE experience (Haubenreich and Engel, 1970). However, effect of fast neutron radiation damage and salt corrosion attack must be investigated for fast MSRs.

Advanced Ni-Mo-Cr alloys are developed and tested in the Russian Federation (Ignatiev and Surenkov, 2017). In the molten Li, Be, U/F and Li, Be, Th, U/F salts with $[U(IV)]/[U(III)]$ ratio ≤ 60 up to temperatures 750 °C the HN80MTY alloy with 1% added aluminum is the most resistant to tellurium intergranular cracking of Ni-base alloys under study (including US Hastelloy N, Chinese GH3535, Czech MONICR and French EM-721 alloys). The metallurgy and in-service properties of these alloys need to be investigated in further details regarding irradiation resistance and industrialization.

The next steps needed to develop these alloys must involve:

- Irradiation, corrosion, tellurium exposure, mechanical property and fabrication tests to finalize the composition for scale up,
- Procurement of large commercial heats of the reference alloy,
- Mechanical property and corrosion tests of at least 10,000 hours duration,
- Development of design methods and rules needed to design a reactor (breeder or burner) to be built of the modified alloy.

Tritium control is an important issue for MSRs because it is the only radionuclide that under normal operating conditions, without failed fuel, has the potential for significant release (Mc Neese et al., 1974). Tritium is generated primarily by the interaction of neutrons with lithium and beryllium in the primary coolant. MSRs will produce significantly more tritium compared to LWRs. Tritium capture at MSR designs is complicated because at high temperatures tritium permeates available structural alloys. The large contact surface area and thin walls of heat exchanger tubes means that heat exchangers will be the primary release pathway. Tritium trapping in the secondary NaF-NaBF₄ coolant was proposed and experimentally proved in molten salt loop by ORNL for the MSBR design.

Fuel salt clean up

The different steps of the fuel salt processing process (except fluorination for which a large experimental feedback from US research work is found in the literature (Mc Neese et al., 1974)) are currently tested in the Russian Federation, France and Euratom laboratories (Ignatiev et al., 2016). The work includes the measurement of actinide and fission product distribution coefficients to evaluate the efficiency of the reductive extraction process using two different liquid pools of bismuth containing lithium as developed by ORNL (Mc Neese et al., 1974). The other steps of the fuel salt cleanup are also tested in Russian and French laboratories such as the back extraction of lanthanides in a chloride or/and fluoride molten salt and the precipitation of lanthanide oxides using bubbling of Ar-H₂O gaseous mixture (Ignatiev et al., 2014). The extraction efficiencies for lanthanides and actinides were estimated using several literature sources leading to the construction of a database available for molten LiF-BeF₂, LiF-BeF₂-ThF₄ and LiF-ThF₄ salt mixtures (Serp et al., 2014).

The coupling of neutronic and salt processing simulation codes in an integrated numerical tool is also used to calculate the extraction efficiencies of fission products, their location in the whole system (reactor and processing unit). Studies are however limited by the uncertainties on the design and knowledge of the complete chemical processing scheme.

The thermodynamic properties of all phases considered in a multi-component system such as the fuel salt have to be assessed in order to collect new data which are necessary for developments of MSR designs, reprocessing scheme and simulation codes. Physical-chemical behavior of fuel salts and in particular coupling between neutronic, thermal-hydraulic and chemistry need to be thoroughly investigated.

Acquisition of fundamental data for the extraction processes is still needed especially for the actinide-rare earth fission products separation. The extraction of rare earth elements has to be done because of the low solubility of these trifluoride elements and their neutron captures that decrease the reactivity balance. This critical step of the pyrochemical process have to be examined both from a thermodynamic and kinetic point of view. The different steps involved in the processing of the fuel salt have not yet been studied from the technological and engineering points of view and will have to be implemented as the system moves from the lab-scale to the industrial scale. Non-proliferation issues related to the fuel salt processing scheme should also be more deeply addressed.

The efficiency of the non-soluble fission products (noble metal and gases) extraction by helium bubbling, which is needed for circuit components life-time and thus safety, will have to be demonstrated in forced convection molten salt loops.

Design and safety

MSRs are very different in the safety approach from solid fuel reactors. In the new MSR concepts developed worldwide, safety will be an essential point to be considered all along the R&D studies. The first step of the safety approach is a systematic description of the reactor components, limited to the main systems surrounding the core, in order to identify the typical accident initiators. The development and the qualification of appropriate simulation tools to study normal and incidental situations have been initiated within the Euratom and the complementary Rosatom projects (Ignatiev et al., 2016). In order to assess the behavior of the fuel salt after reactor shut down, a tool based on point kinetics able to calculate the decay heat have been developed and validated for fast spectrum MSR. Loss of heat sink transients can be calculated allowing the evaluation of their impact on the fuel salt temperature. These residual heat calculations will be the basis for the design of the safety draining system, as drainage of the salt is foreseen for reactor shut down, whether in normal or in incidental conditions.

Complete pre-conceptual designs of MOSART and MSFR do not yet exist. However, initial candidate technologies have been identified for all required MOSART and MSFR functions. Substantial uncertainty remains in key elements of plant design and technology implementation. Developing a complete conceptual design will provide a unifying framework to enable an integrated set of technology choices to be made. Concept development also identifies technologies that require longer term development (e.g., structural alloy creep testing) that, in turn, assist in determining the overall timeline for development and deployment of the MSR.

The licensing-related design and safety features of liquid fueled MSR combine those of a reactor and a chemical processing plant. The MSR safety approach will have to take into account a fuel in a liquid form within the coolant which depends upon keeping actinides and fission products in solution.

Several categories of active components are needed to be qualified for the operation of MSRs like heat exchangers, pumps, valves. These items face the same thermal and chemical compatibility challenges as the instrumentation equipment. Among these, the heat exchangers are likely to represent the most significant challenges. A heat exchanger is a cold spot in the system and supports a significant heat flux, both factors that can drive corrosion and corrosion product deposition. In addition, the heat exchangers may be required to provide a barrier for tritium diffusion to control tritium releases to the balance-of-plant and the environment. The designs must also allow inspection and be serviceable in the event of plugging of tubes or MS leaking. These challenges are compounded by a desire to maximize the thermal efficiency of the heat exchanger by minimizing its wall thickness and maximizing its surface area.

For all MSRs, the general principle of operation is the same (Serp et al., 2014):

- A fuel circuit where the liquid fuel is located during normal operation and circulates between a first zone where the criticality is reached, and a second zone where the heat of the salt is exchanged with a secondary salt through exchangers. In this second zone, there are also delayed neutrons and residual power on the contrary to classical solid-fuel reactors.
- An intermediate circuit with a cooling salt that will extract heat from the fuel circuit via exchangers and transmit it to a steam generation circuit to produce steam either for electrical use or for other applications. This last circuit is named classically “energy conversion circuit”.
- In the chemical processing unit, several operations can be made with the fuel salt, such as extraction of some soluble fission and corrosion products, control of the salt composition, and injection of fresh fissile and possibly fertile materials necessary to keep the salt liquid without solid accumulation over the operation temperature range and to maintain criticality for the continued operation.

MSRs provide unique challenges in terms of the safety evaluation:

- Compatibility of salts with reactor materials (at high temperatures and radiation damage).
- High melting point.
- Significant quantities of fuel outside the reactor core: heat exchanger, various tanks, pumps, possible associated fuel processing; possible continuous addition/removal of fuel.
- Distributed delayed neutrons (mobile fuel).
- Salt vapor deposition in cover gas lines.
- Potential for larger volumes of high activity components (filters and replaceable components).
- Fuel composition continuously changing.
- Fuel performs cooling function.
- Tritium production (lithium and beryllium containing fuel salts).
- Presence of bubbles (fission product gasses) passing through the core.
- Noble gas fission products evolve out of the salt into cover gas; noble metal fission products plate out onto surfaces; fuel salt retains most other fission products. The fuel salt processing units both for gaseous and soluble fission products including actinides recycling requests a specific safety analysis.
- The fuel salt composition is complex and some products could get their solubility limit leading to uncontrolled deposition in a cold spot or by selective extraction during salt cooling procedures. If this would happen with fissile elements that have low critical masses, it could create criticality accident.
- The notion of barrier remains to be specified, the aim being to avoid any significant radiological releases in any situation.
- The precise operating mode of these reactors remains to be investigated.

For the MOSART and MSFR, which have a fast neutron cores, the criticality in the critical zone of the fuel circuit is a function of the shape of this critical zone and temperature. According to the parameters, the criticality is linked to a precise value of the temperature of the fuel salt. At a higher temperature, the salt is too diluted, inducing lower density of fission matter, then the reactivity goes down inducing a lower production of heat and a decrease of the temperature of the fuel salt. At a lower temperature, the fuel salt is too dense, inducing higher density of fission matter in the critical zone, then the reactivity goes up inducing a higher production of heat and an increase of the temperature of the fuel salt. The higher the feedback effect coefficient, the shorter the response time of the system to return to its equilibrium state. The temperature of the fuel linked to the criticality is called “critical temperature”.

Some differences in design, or even in neutron behavior, will emerge between thermal spectrum and fast spectrum concepts. Thermal flux reactors have a moderator in their criticality zone, such as graphite elements, and are very sensitive to fission products poisoning. A prototype, MSRE, was operated in the United States at ORNL during the 1960s. This is so far the only MSR experience feedback. In addition, fast reactors are less sensitive to fission product poisoning and accept a longer removal times.

Control of reactivity function

Regarding the neutron characteristics, the negative reactivity feedback effect of the MOSART and MSFR, coming from the density effect and the Doppler effect, provides intrinsic reactor stability. Unlike solid-fuel reactors, the high negative density feedback coefficient acts instantaneously in the case where the fuel salt also acts as coolant.

Also in such a circulating-fuel system, the fraction of delayed neutrons is reduced because the fuel motion drifts a part of the delayed neutron precursors to low importance areas. Reactivity insertion up to 1000 pcm ($0.01 \Delta k/k$) has been calculated and results shows that the equilibrium state can be restored without involving a large temperature increase.

This negative and instantaneous temperature feedback effect has several consequences on the MOSART and MSFR designs:

- Control rods may not be necessary; the control of the reactor being carried out by simply controlling the power extraction via heat exchangers. If the cooling increases, the power will increase to maintain the critical temperature. By contrast, if the cooling stops, it will have the opposite effect and the reactor power drops to zero (excluding residual power) without large temperature increase
- The reactor can be started up by progressive filling until the criticality is reached.

A possibility of draining of the salt is necessary for maintaining a sub-critical state. On the other hand, the salt chemistry is complex. The salt contains products with low critical masses, such as plutonium, uranium or other minor actinides. In case of deposition of these products for example in the cold zones of heat exchangers, criticality could occur. It will therefore be necessary to take measures both to avoid this type of accident and to mitigate their consequences.

Decay heat removal function

In the event of a reactor shutdown, the residual power will be distributed throughout the fuel circuit. Good physical properties of the liquid fuel make it possible to organize efficient heat removal based on natural circulation. Various devices must then evacuate it. The fact that the salt does not have any exothermic reaction with air is favorable for cooling by air. Natural circulation of salt, covering gas and air has to be investigated. The gas cooling could be directly done with the fuel salt or through an intermediate salt circuit. Using the air as heat sink requires investigating how the confinement function is achieved at this level.

Containment function

In the MSR, the first barrier is the fuel system, which plays the role of the cladding of a solid fuel. However, certain elements would have to be taken into account in the analysis of by-pass or weak points of this first barrier. This includes:

- Plates or tubes of heat exchangers;
- The pump and the pump shaft;
- Sampling and reintroduction systems for combustible and fertile salts;
- The removable cover in the upper reflector;
- The gas sampling system of the salt treatment unit;
- Valves and lines connecting the fuel system to the storage tanks of combustible and fertile salts;
- The valve and the pipe connecting the cover gas of the fuel circuit;
- Salt drain valves.

The difficulty lies in the definition of the second barrier. This must include the first barrier, in particular the heat exchangers, the draining circuit and allow interventions in case of leakage of the liquid fuel. The draining of the core appears necessary, either for the maintenance and inspection (e.g., replacement of protective baffles of the tank in the critical zone), or in case of leakage to minimize the leak of fuel between the first and the second barrier, or for maintaining the salt in a sub-critical state. The problems

of solid species that could be formed during cooling and or remain during liquefaction of the fuel salt for reinjection will have to be analyzed and specified. In conclusion, this second barrier will be necessary more for operation and maintenance than for safety analysis. The last barrier will be the containment that allows avoiding any radioactive large release.

Proliferation challenges

The reference US ORNL designs of a breeder (MSBR) and denatured (DMSR) MSRs developed in the 1970s clearly illustrate disadvantage and advantages in terms of fuel material attractiveness for the case of U-Th fuel cycle. The low material attractiveness DMSR fuel cycle has been incorporated in some of the new MSR designs. Fuel salt additions in MSRs become part of a homogeneous mixture upon being added to operating fuel, so bred fissile isotopes cannot be readily chemically separated from non-fissile isotopes. Isotopes with higher fission cross sections tend to preferentially burn out lowering the fissile actinide fraction generating deep-burn fuel over time. Development of a lower fissile fraction plutonium isotopic composition tends to happen faster in thermal spectrum reactors because their fissions are dominantly generated from fissile materials whereas the fast spectrum systems consume both fissile and fissionable nuclei.

Today wide variety of MSRs, in which a flowing molten salt mixture based on fluorides or chlorides contains fissile/fertile material serving as fuel and coolant, have begun development around the world (see Table 1). The proposed new MSRs have widely varying fuel cycles to the point that identifying common elements is challenging. Proposed neutron spectra range from thermal to fast and also include time varying spectra. Almost every known form of fissile/fertile material or fuel cycle is under consideration as a fuel source.

Several of the prospective vendors (see Table 1) have indicated that they intend to employ a Th-²³³U breeding equilibrium fuel cycle. Breeding ²³³U from thorium, however, continues to involve creating a separated stream of ²³³Pa that is allowed to decay in a lower thermal flux region. Separated ²³³Pa has high material attractiveness.

Basic information is provided concerning fuel cycle of the MOSART power plant (Ignatiev et al., 2019) integrated with facilities of Experimental Demonstration Centre (EDC) (see Fig. 2). The EDC is under construction in Russia at the site of the Mining and Chemical Combine (MCC) and after 2020 will begin reprocessing of spent nuclear fuel (SNF) from VVER-1000 reactors on the basis of innovative technology, providing a recovered nuclear material (refined products) for recycling in thermal and fast solid fuel reactors. In accordance with the EDC flowsheet, the highly active raffinate, containing long-lived minor actinides, is sent for conditioning. Use of dedicated reactor unit as a TRU burner, remaining after the main part of uranium and plutonium recycling to solid fuel thermal and fast reactors, may reduce the volume and radiotoxicity of HLW. The principle attraction of the MSR technology in this application is the use of fuel material flexibility (easy of “short cooled” fuel preparation, processing and multiple recycling) for gaining additional profits as compared with solid materials.

It is proposed to use the technical and technological capabilities of the MCC site to place single fluid fertile free MOSART system in the immediate vicinity of SNF aqueous reprocessing plant, linking it to the EDC infrastructure. The main design objective of the single fluid 2400 MWt MOSART is to close nuclear fuel cycle for all actinides, including neptunium, plutonium, americium and curium. It is assumed that the fuel cycle of this complex will be organized as follows (see Fig. 1): the bulk of the removed uranium and plutonium return to thermal and fast solid fuel reactors, and the remaining transuranic elements are transferred for utilization in the MOSART system. The co-location of MOSART and SNF reprocessing plant, will provide the MCC site and the surrounding customers by electricity (7.92 TWe hours per year), facilitates the problems of nuclear materials transport and radwaste management. As with fluid fluoride-based fuel the entire fuel element fabrication process is excluded, providing for exceptional flexibility. The fuel can be blended into reactor straightly as needed at any time. Also, there is no need for long cool times and interim storage. This saves for MOSART significant part of the front-end effort (including radioactive doses) and cost. All fresh fuel fluorides containing significant quantities of fissile materials for initial loading and make-up, will be manufactured onsite at the EDC by hydro-fluorination process.

The main advantages of MOSART are the ability to vary widely the minor actinides content in fuel salt without losing the inherent safety and the absence of stages related to the fuel fabrication and re-fabrication in multiple actinides recycling. As result there are significant proliferation resistance and safeguards implications related to the fuel make-up and chemical processing in MOSART plant: (1) there will be continuous variation of isotopic concentrations in the fuel salt from both actinides transmutation and chemical processing; (2) refueling scheme include the ability to continuously feed the core with fresh fissile material; (3) plate-out of noble metals in the primary circuit could complicate inventory tracking.

Fuel salt represents a unique combination of high-temperature and high-radiation environments that will be challenging for diversion as well as measurement techniques and instrumentation: (a) temperature in the reactor or fuel processing plant will always be kept in liquid state within 650–750 °C; and (b) fuel salt will be highly radioactive even outside the primary circuit.

Note, that after each recycling fuel is getting less attractive for fissile material diversion. During 50 years of operation 2400 MWt MOSART can utilize more than 12 t of minor actinides. Last TRU loading will be transferred to the next MOSART unit to be constructed at the MCC site.

In order to avoid nuclear matter diversion, the MOSART reactor plant is integrated (1) at the front end with VVER SNF aqueous reprocessing plant and (2) at the back end with the high temperature fuel salt clean up facility all located at the MCC site. All fresh fuel fluorides containing significant quantities of fissile materials (plutonium plus minor actinides) for initial loading and make-up,

Fig. 2 Nuclear fuel cycle with MOSART at MCC site.

will be manufactured onsite by hydrofluorination process. In molten salt pyroprocessing facility the higher actinides would always accompany the plutonium, this operation would never produce a “clean” material that would be attractive for diversion.

Conclusion

Molten salt fluorides as coolants offer interesting features such as very good transport properties, strong irradiation resistance, high thermal stability and boiling points. They share some advantages with liquid metal coolants like reactor operation at low pressure. This constitutes a significant safety and cost advantage.

The MSR has many advantages compared to other reactor types, like the capability of burning actinides or breeding fissile fuel, continuous processing of spent fuel, no need for fuel manufacturing, safe operation, and a high level of sustainability because MSR can be run as a transmuter of long-lived actinides from used nuclear fuel or as a breeder reactor in the uranium fuel cycle or (much better) in the thorium fuel cycle. World-wide, all these operation modes of the MSR are investigated. The MSRs with liquid fuel can be designed with a neutron spectrum ranging from thermal to fast.

The thermal spectrum approach has a larger historic development foundation and ability to significantly lower neutron flux reaching reactor vessel material compared to fast spectrum MSR. The thermal spectrum designs, like IMSR and ThorCon, open the possibility of simplified converter options, removing the need for fuel processing by employing LEU, on its own or in combination with thorium. Converter MSR designs also allow consideration of SS316 as container material for reactor vessel and carrier salts that is free from the need for enriched lithium 7 and/or beryllium (and their tritium production) as neutron economy is of lower importance for converters.

Over the last years, R&D on MSRs has been mainly focused on fast spectrum concepts with or without thorium support (MSFR and MOSART), which have been recognized within GIF as long term alternative to solid-fueled fast neutron reactors with attractive features (strongly negative reactivity feedback coefficients, smaller fissile inventory, simplified fuel cycle). A negative coolant temperature reactivity coefficient is universally recognized as a desirable safety feature for power reactors. MSFR and MOSART can operate within technical limits using high nickel alloy as container material with different fuel loadings and make-up based on TRUs (from used LWR fuel with MA/TRU ratio up to 0.45) as special actinide transmuter, as self-sustainable system ($CR = 1$) or even as a breeder ($CR > 1$).

The risks of corrosion by the impurities (oxygen, water mainly) dissolved into a molten salt coolant or by the fission products present in fuel salt are a significant issue in MSRs that has been the subject of R&D work since the 1950s. The R&D on advanced

materials for MSR designs are under way now in different countries. Although more experimental and qualification efforts for special materials involved in the MSR design are still needed to demonstrate the viability of MSRs, past experience gained at the ORNL in the 1960s and 1970s remains a source of knowledge that demonstrated many positive aspects of the reactor technology.

The safety analysis methods in their current form cannot be applied to liquid fueled MSRs, in particular due to the fact that the fuel is molten during normal operation. Its outstanding safety level is ensured by the strongly negative reactivity feedback coefficients, even in a fast neutron spectrum, and the capability to drain the liquid fuel into dump tanks, which excludes overheating due to stagnant decay heat removal. A novel methodology for the design and safety evaluations of liquid fueled MSRs is needed, relying on current accepted safety principles such as the principle of the defense-in-depth, the use of multiple barriers and the three basic safety functions: reactivity control, decay heat removal and radioactive products confinement. New methodology applied to the reactor and reprocessing units shall be robust and comprehensive, integrate both deterministic and probabilistic approaches.

MSR designs under considerations, in which a flowing molten salt mixture based on fluorides contains fissile/fertile material serving as fuel and coolant, represent a reactor plant integrated with a pyro processing unit. Existing IAEA PR&PP approaches are mainly applicable to the U-Pu, but not to MA-based and Th-U fuel cycles, and to item counting for solid fuel reactors, as well as to bulk material accountancy for the front and back end of the nuclear fuel cycle. These techniques and associated instrumentation for bulk accountancy have been developed predominantly for enrichment, fuel fabrication, and aqueous reprocessing. However, none of these bulk accountancy measures can be directly applied to high temperature MSR designs, in general, and for MSFR and MOSART in particular, without evaluation and potential modification. Almost no work has been done to determine how will the fissile material content in the fuel salt mixture be determined, when it is in the primary circuit, in drain tanks, or in processing unit.

The various MSR projects have common themes in basic R&D areas, of which the most prominent are the liquid salt technology and materials behavior, the fuel and fuel cycle chemistry and modeling, and the numerical simulation and safety design aspects of the reactor. Research in these areas will not only support the development of this particular reactor and fuel cycle technology, but can find applications in other Generation IV systems as well, like the SFR (Heidet, 2021), LFR (Alemberti, 2021) and VHTR (Fütterer et al., 2021), for example, for the development of alternative fluids for intermediate heat transport, where liquid salts offer potential advantages regarding in particular the high volumetric heat capacity, reduced equipment size, absence of chemical exothermal reactions, intermediate loop and power cycle coolants.

The strong international cooperation between the countries involved, has shown to be very effective in tackling the most prominent remaining R&D issues. However, a continued effort is needed by all parties to converge to a basic reactor design excelling in safety and sustainability around 2025–30.

Introduction

The Super-Critical Water-cooled Reactor (SCWR) is a high temperature, high-pressure water-cooled reactor that operates above the thermodynamic critical point (374 °C, 22.1 MPa). It is evolved from the current fleet of nuclear reactors (such as boiling-water reactors (BWRs), pressurized-water reactors (PWRs) and pressurized heavy-water reactors (PHWRs)), which has accumulated over 50 years of design and operating experience. The balance of plant configurations of SCWRs are based on those of the supercritical water fossil-fuel power plants. This has simplified significantly the development process, which focuses mainly on the reactor core, and could expedite the deployment.

Fig. 1 illustrates two types of SCWR core concepts that are being considered (GIF, 2014): pressure-vessel (PV) type and pressure-tube (PT) type. Other than the reactor core internals, the overall plant configurations are the same for both types.

The flexibility of SCWR designs accommodates traditional (i.e., uranium oxide (UO₂)) and advanced (i.e., thorium and plutonium-uranium mixed oxide (MOX)) fuel cycles with thermal, fast and mixed spectra. Selected parameters for various conceptual designs are summarized in Table 1. All SCWR concepts are designed to operate at reactor outlet temperatures between 500 and 625 °C matching closely the current and advanced supercritical-pressure turbines. This range of reactor outlet temperatures would improve the thermal efficiency ranging 43–48%, compared to 33–35% for the current fleet of nuclear reactors. The UO₂ fuel composition is similar to those used in Gen-III and Gen-III+ nuclear-reactor technologies. A mix of thorium and plutonium oxides, (Pu,Th)O₂, is adopted as the fuel composition for the pressure-tube type SCWR. Light water (H₂O) is used as coolant and moderator for the pressure-vessel type thermal-spectrum SCWR. However, light water is used as coolant while heavy water (D₂O) is adopted as moderator for the pressure-tube type SCWR.

The safety approach is based on that of the Gen III + nuclear-reactor technology but includes additional passive safety systems. This could reduce the core damage frequency for postulated design-basis accidents compared to the current fleet of nuclear reactors. The compact design of the SCWR core and the elimination of certain systems (e.g., steam generators as in PWRs and recirculation

pumps and steam separators/dryers as in BWRs) have led to reductions in the footprint and containment size. This has positive implications for protection against external events in addition to the reduction in capital cost.

The main improvement in the SCWR is in the area of economics due to its high thermal efficiency and plant-design simplifications that result from the use of supercritical (SC) water as coolant (GIF, 2014). Furthermore, the safety characteristics of the SCWR have also been advanced through the introduction of additional passive safety systems. Depending on the concept configuration, the aspect of proliferation resistance and physical protection (PR&PP) has also been improved.

Historical developments

The SCWR development can be divided into two stages. The first stage covered earliest proposals of the SCWR concept in 1950s and 1960s (Oka et al., 2010; Schulenberg et al., 2014). These proposals included a light-water moderated, supercritical-steam-cooled reactor (which was designed at Westinghouse in 1957) with 538 °C outlet temperature to generate 70 MW thermal power, a heavy-water-moderated, light-water cooled reactor (which was designed at General Electric in 1959) to generate thermal power of 300 MW, a graphite moderated, light-water-cooled pressure-tube reactor (which was designed at Westinghouse in 1962) to generate electric power of 1000 MW, and a light water cooled and moderated pressurized water reactor (which was proposed at Westinghouse in 1966) at supercritical pressure to generate 800 MW electric power. In addition, a supercritical water cooled

in-pile fuel testing loop was constructed and installed in the Saxton Research Reactor for irradiating collapsed clad fuel elements in a reactor environment but the program was suspended in April 1965 after a shutdown of the loop (Cohen, 1968).

The second stage was initiated as a means to improve fuel utilization and reduce capital cost (Oka et al., 2010). Many countries participated in the development after the SCWR was selected as one of six advanced nuclear-reactor systems for collaborative R&D in the Generation-IV International Forum (GIF) (GIF, 2014). The first SCWR development proposal was introduced in 1986 at USSR for the design of a two-circuit reactor plant (VVER-SCP-I) to generate electric power of 500 MW (Ryzhov et al., 2011). A thermal neutron spectrum and later an alternative concept with a fast neutron spectrum, light water cooled, pressure vessel type SCWRs were proposed in the late 90s at the University of Tokyo (Oka et al., 2010). From 1999 to around 2006, a multi-year program was initiated to support the development of the SCWR in USA (Buongiorno and MacDonald, 2003). The European Commission supported a consortium of European research institutes and industrial partners to develop a pressure-vessel type SCWR, which is referred to as the High Performance Light Water Reactor (or HPLWR) in 2000 (Schulenberg and Starflinger, 2012). In 2006, Research and Development Institute of Power Engineering (RDIPE) in the Russian Federation developed a concept of supercritical water-cooled and graphite-moderated power reactors (VGERs) operating at the pressure of 25 MPa and outlet temperature of 550 °C (Ryzhov et al., 2011). Natural Resources Canada (NRCan) established a national program (Generation-IV National Program) in 2006 to support Generation-IV R&D and develop a SCWR concept based on the pressure-tube configuration (Leung et al., 2018a). In 2007, Shanghai Jiao Tong University along with other institutes performed the basic research of SCW and proposed a mixed-spectrum SCWR core concept (Cheng et al., 2007). In 2012, a thermal-spectrum SCWR conceptual design, referred to as the CSR1000, was established at Nuclear Power Institute of China (IAEA, 2015).

Thermodynamic cycle

The thermodynamic cycle of a SCWR is basically the same as that of a supercritical fossil plant (IAEA, 2014). Superheated steam at a pressure of 24–25 MPa and a temperature of 500 °C or more from the reactor outlet is supplied directly to the High Pressure turbine (HP), then to the Intermediate Pressure turbine (IP) and afterward to the Low Pressure turbine (LP). The internal energy of the superheated steam is converted to kinetic energy of turbine rotor and then to electric power through the Generator (G). A moisture separator and reheater is installed between the high pressure and the intermediate-pressure turbines or between the intermediate pressure and the low-pressure turbines, depending on the steam quality, to reduce the moisture content before entering the downstream turbine. Steam exhausted out of the low-pressure turbine at low pressure (~abs 5 kPa) and temperature (~33 °C) is further cooled in the condenser. The condensate pressure is increased to 25 MPa by the Condensate Extraction Pump (CEP) and the Feedwater Pump (FP). Several preheaters (PHs) with turbine steam extractions are introduced to heat up the water temperature to the designed value ranging from 280–350 °C. This heat recovery process increases the reactor inlet temperature and thus the reactor average temperature and thermal efficiency. A general sketch of the SCWR steam-cycle concept is shown in Fig. 2 to illustrate the once-through design principle.

Thermodynamic cycle designs for SCWR concepts are similar to each other. As mentioned above, the location of the moisture separator and reheaters could be different. Furthermore, seven (three low pressure and three high-pressure preheaters with the deaerator in between), eight (four low pressure and three high-pressure preheaters with the deaerator in between) or nine (four low pressure and four high-pressure preheaters with the deaerator in between) heat recovery stages could be implemented (IAEA, 2014).

Fig. 2 Simplified energy conversion system for typical SCWR designs.

SCWR core concepts

The SCWR thermal-spectrum core concepts have been based mainly on the pressure-vessel configuration (Schulenberg and Leung, 2016). However, the one developed in Canada is based on the pressure-tube configuration. Coolant is circulated from the bottom to the top of fuel assemblies in a single path for both Japan's and Canada's concepts (Schulenberg et al., 2014). It passes through two zones of fuel assemblies (two-path system) in China's concept (IAEA, 2015) and three zones (three-path system) in EU's concept (Schulenberg and Starflinger, 2012). Fig. 3 illustrates the thermal-spectrum core configurations (Leung et al., 2018b).

Canada's concept consists of an inlet plenum, where the coolant enters into the core and distributes to the fuel channels, and an outlet header, which collects the high-temperature coolant from the fuel channels and directs to the high-pressure turbine (Schulenberg and Leung, 2016). The fuel channels are submerged within the low-pressure heavy-water moderator in the calandria vessel. Control and shutdown rods are inserted from the side of the calandria vessel into the low-pressure moderator.

Both China's and EU's core concepts have a similar configuration, except that China's core is divided into two zones (IAEA, 2015), while the EU's core into three zones (Schulenberg and Starflinger, 2012). Coolant enters the vessel from the inlet nozzles and is divided into two streams. In China's concept, the majority of coolant travels up the passage besides the vessel wall and down through the first zone of fuel assemblies (IAEA, 2015). It mixes with the remaining coolant in the lower plenum and travels up through the second zone of fuel assemblies. The remaining coolant entering the vessel travels down to the lower plenum and mixes with the bulk coolant. In EU's concept, most of the coolant travels down the passage beside the vessel wall and up through the first zone of fuel assemblies (Schulenberg and Starflinger, 2012). The remaining coolant flows up another passage to the top of the vessel, mixes with the coolant through the first zone, down through the second zone and up through the third zone of fuel assemblies. The high-temperature coolant collected at the outlet header is directed to the high-pressure turbine. Control and shutdown rods are inserted from the top of the vessel into the core.

Japan's core concept is similar to that of a boiling water reactor (Yamada et al., 2011). Coolant enters the vessel from the inlet nozzles and is divided into two streams. Most of the coolant travels down the passage beside the vessel wall. It mixes with the

Fig. 3 Thermal-spectrum SCWR core configurations (Leung et al., 2018b).

remaining coolant at the lower plenum and travels up through the fuel assemblies. The remaining coolant entering the vessel flows up another passage to the top of the vessel and then down to the bottom of the vessel along the wall mixing with the bulk coolant. It cools the vessel wall and maintains the wall at low temperatures. The high-temperature coolant exiting the fuel assemblies is collected in the outlet header and is directed to the high-pressure turbine. Control and shutdown rods are inserted from the bottom of the vessel into the core. There is an option for a two-path core configuration, which is similar to China's SCWR concept.

The flexibility of SCWRs facilitates the development of mixed- and fast-spectrum core concepts, as illustrated in Fig. 4, other than thermal-spectrum core concepts (Schulenberg and Leung, 2016). A mixed-spectrum SCWR core concept is being developed at the Shanghai Jiao Tong University in China (Cheng et al., 2007). Its configuration is similar to that of China's thermal-spectrum core. The first zone of fuel assemblies is the thermal-spectrum region while the second zone is the fast-spectrum region. Control and shutdown rods are also inserted from the top of the vessel to the core.

The configuration of Japan's fast-spectrum core concept differs from that of the thermal-spectrum core concept (Oka et al., 2010). It is separated into two zones with a two-path flow pattern (similar to that of China's thermal-spectrum core configuration). The first zone consists of separated seed and blanket fuel assemblies with the downward coolant flow, while the second zone consists of seed fuel assemblies with the upward coolant flow. Control and shutdown rods are inserted through the top of the vessel into the core (unlike Japan's thermal-spectrum core where the rods are inserted through the bottom of the vessel).

Russian Federation's fast-spectrum core concept has the option of adopting the single-path or two-path flow pattern (Ryzhov et al., 2011; Glebov et al., 2015). For the single-path core concept, the coolant entering the core travels to the top of the vessel and then directs to the bottom of the vessel. It flows upwards through the fuel assemblies and discharges to the high-pressure turbine. For the two-path core concept, the coolant entering the core is separated into two streams. The majority of the coolant travels up to the top of the vessel and then downward through the outer zone of fuel assemblies. The remaining coolant flows down through the passage beside the vessel wall. It mixes with the bulk flow and travels upward through the inner zone of fuel assemblies.

SCWR fuel assembly concepts

Fuel concepts for thermal-spectrum cores of the pressure-vessel type of SCWRs resemble closely to those of light water reactors. Fig. 5 illustrates the fuel assemblies for thermal-spectrum cores of SCWR (Schulenberg and Leung, 2016). Uranium fuel with various levels of enrichment and neutron absorber has been included in the pellets. Differences are mainly in the spacing devices and the introduction of a water rod at the central region of the fuel assembly to enhance the moderation of the coolant at high pressure and high-temperature conditions.

The fuel concept for Canada's SCWR consists of a "flask"-like structure that contains the fuel assembly and is connected to the outlet header (Schulenberg and Leung, 2016). Several nozzles are introduced for the coolant entering into the structure. These nozzles also serve as orifices to control the flow rate matching the power generation in the channel (another set of openings are also installed at the top of the pressure tube). The fuel assembly resembles to fuel bundles of the heavy-water reactors with two rings of 32 fuel rods and an active length of 5 m. Spacing between fuel rods is maintained with a wire-wrapped spacer. A central flow tube is installed for the coolant to travel down from the nozzles to the bottom of the fuel channel. Furthermore, this improves the moderation for the inner-ring rods resulting in a balanced radial power profile. The coolant travels upward through the fuel

Fig. 4 Mixed- and fast-spectrum SCWR core configurations (Leung et al., 2018b).

Fig. 5 Thermal-spectrum SCWR fuel concepts (Schulenberg and Leung, 2016).

assembly to the outlet header, and is discharged to the high-pressure turbine. Pellets inside the fuel element consist of a mixture of thorium and plutonium (15 wt% on average).

The fuel-assembly concept of China's thermal-spectrum SCWR is configured into a square array of 56 fuel rods (IAEA, 2015). Wire-wrapped spacers are introduced to maintain the gap size between fuel rods. A water rod is installed in the central region to increase the moderation. Pellets in the fuel rod consist of enriched uranium and are similar to those of light-water reactors. Each pellet has a central hole to reduce the fuel centerline temperature. Four assemblies are grouped together with a boiling-water-reactor type of control-rod configuration.

The fuel assembly concept of EU's thermal-spectrum SCWR has a square-array configuration with 40 fuel rods (Schulenberg and Starflinger, 2012). Wire-wrapped spacers are also used to maintain the gap size between fuel rods. A water rod is installed in the central region to increase the moderation. Pellets in the fuel rod consist of enriched uranium and are similar to those of light-water reactors. Nine assemblies are grouped together with common head and foot pieces.

The fuel assembly concept of Japan's thermal-spectrum SCWR is the largest among all concepts (Yamada et al., 2011). It consists of 192 fuel rods and resembles closely to that of the boiling water reactor. Grid spacers are used to maintain the gap size between fuel rods. A water rod is installed in the central region to increase the moderation. Pellets in the fuel rod consist of uranium fuel of various levels of enrichment. Several rods contain only neutron absorbers for initial reactivity suppression. Four assemblies are grouped together with a boiling-water-reactor type of control-rod configuration.

Fuel assembly concepts for mixed- and fast-spectrum SCWRs are illustrated in Fig. 6 (Schulenberg and Leung, 2016). Two separate fuel assemblies are proposed for China's mixed-spectrum SCWR; one for the thermal zone and the other for the fast zone (Cheng et al., 2007). The fuel assembly concept for the thermal zone consists of 180 fuel rods with nine water rods distributed within the assembly. Wire-wrapped spacers are used to maintain the gap size between fuel rods. Pellets in the fuel rod consist of enriched uranium. Three grades of enriched uranium pellets are inserted at different levels of the fuel rod (i.e., lower grades at the top where the coolant temperature is the highest and higher grades at the bottom). The fuel assembly concept for the fast zone consists of 324 fuel rods. Wire-wrapped spacers are used to maintain the gap size between fuel rods. Each fuel rod contains both the seed and blanket pellets wafered in different sections. Mixed oxide fuel is used for the seed pellet and depleted uranium fuel for the blanket pellet.

Fig. 6 Mixed- and fast-spectrum SCWR fuel concepts (Schulenberg and Leung, 2016).

Two separate fuel-assembly types are introduced for Japan's fast-spectrum SCWR: seed assemblies each with 252 fuel rods and blanket assemblies each with 127 fuel rods (Oka et al., 2010). These fuel assemblies are configured in hexagonal arrays. Mixed oxide fuel and stainless-steel cladding are used for seed fuel rods, and depleted uranium and stainless-steel cladding are used for blanket fuel rods. In the blanket assembly, the fuel rod region is surrounded by a solid moderator (Zirconia Hydride layer) so that fast neutrons coming from the seed fuel are slowed down and are absorbed by the blanket fuel without causing fast fissions. It enables the fast-spectrum SCWR to have a negative void reactivity without adopting a flat core shape or additional devices. Nineteen control rods are inserted into each seed fuel assembly.

The fuel assembly concept for Russian Federation's fast-spectrum SCWR is configured into a similar array to that of Japan's seed fuel assembly (i.e., 252 fuel rod in a hexagonal array) (Ryzhov et al., 2011). However, only one fuel assembly is adopted with seed and blanket fuel layers wafered in each fuel rod. Mixed-oxide fuel is used for the seed layers and depleted uranium with zirconium hydride is used for the blanket layers. Nineteen absorber or zirconium hydride rods are inserted into the fuel assembly.

SCWR safety system concepts

Safety-system concepts of SCWRs are evolved from the Gen-III and Gen-III+ nuclear reactor systems. Additional passive safety systems have been incorporated to enhance the safety characteristics. Deterministic and probabilistic safety analyses were performed for the Canadian SCWR, HPLWR and JSCWR. Schematic diagrams of SCWR containment and safety system concepts are shown in Fig. 7.

Fig. 7 SCWR containment and safety systems.

Main components of the Canadian SCWR safety system consist of the containment pool, reserve water pool, isolation condensers and passive cooling systems (Schulenberg and Leung, 2016). The containment pool is an annular-shape tank that is located in the containment building above the reactor. Steam condensers and passive autocatalytic recombiners are housed in a condenser gallery located above the pool liquid level. The condenser gallery floor has a series of drains equipped with suppression nozzles, discharging into the containment pool below the liquid level. The containment pool is also used as the pressure suppression pool and the water source for the gravity-driven core flooding system. The reserve water pool serves as a buffer between the passive safety systems and the ultimate heat sink. It is located in the upper section of the shield building and occupies an annular space against the building outer wall. The pool is divided into two sections, each section housing one train of isolation condensers (ICs) and the passive moderator-cooling system (PMCS). Each train of the IC system consists of a piping loop running from the reactor outlet, to heat exchangers and returning to the reactor inlet. The IC relies on the difference of densities between the IC hot leg and cold leg to initiate and maintain a gravity-driven circulation. The PMCS consists of a piping loop running from the reactor calandria to heat exchangers located in the reserve water pool and returning to the calandria. The PMCS uses a flashing-driven natural circulation loop to remove heat from the moderator transferred from the cladding through radiation. The atmospheric air heat exchangers are designed to reject heat from the reserve water pool to the atmosphere which serves to extend the period of time in which the water pool can function as a heat sink before intervention under a high core decay heat regime.

The safety system of CSR1000 adopts the idea of passive and active measures both in PWRs and BWRs (IAEA, 2015). It includes five main systems: High-Pressure Injection System (HPIS), Automatic Depressurization System (ADS), Passive Core Cooling System (PXS), Pressure Suppression Type Containment System (PCS) and Reactor Pit Injection System (PIS). The high-pressure injection system consists of two high pressure feedwater tanks (RMT), each of which is connected to the reactor coolant circuit loop. Each high-pressure feedwater tank (RMT) is filled with high-pressure water and is located above the reactor core. The Automatic

Depressurization System composes of a series of Safety Relief Valves (SRV) and Depressurization Valves (DPV). The SRV are used to protect the circuit from over-pressurization and DPVs are used to accelerate the depressurization process from supercritical pressure to ambient pressure. The Passive Core Cooling System (PXS) composes of the Passive Residual Heat Removal (PRHR) subsystem and passive reactor injection subsystem. The PRHR subsystem removes the residual decay heat from the reactor to the condensation pool through a passive heat exchanger (PRHR HX). The passive reactor injection subsystem connects the condensation pool directly to the reactor with a passive reactor injection line. When the reactor core system (RCS) depressurizes to the atmospheric pressure, it could provide enough water for cooling the reactor. The CSR1000 containment is of pressure suppression type composed of reactor pit, wet well and dry well. The reactor pit is used for containing the reactor vessel. The dry well is used for containing the RCS components and some safety system components. The wet well has a large condensation pool for suppressing the containment pressure when the steam is discharged from the RCS to the containment.

The HPLWR compact containment contains the reactor pressure vessel, an annular pressure suppression pool, four upper pools and a drywell (Schulenberg and Starflinger, 2012). Four feedwater lines with check valves and four steam lines with containment isolation valves, each inside and outside of the containment, connect the reactor with the steam cycle. Four automatic depressurization systems (ADSSs), each equipped with two safety relief valves and two depressurization valves, open to eight spargers in the upper pools. Four redundant and independent low-pressure coolant injection pumps supply coolant from the pressure suppression pool via a heat exchanger and a check valve to the feed-water line for the purpose of residual heat removal. Overflow pipes from the upper pools to the pressure suppression pool close the coolant loop inside the containment. Sixteen vent tubes connect the drywell with the pressure suppression pool for pressure suppression in case of loss-of-coolant accidents (LOCAs), as well as a discharge of hydrogen from the drywell to wetwell. The pressure suppression pool can also be vented to the stack through aerosol and iodine filters. Four emergency condensers are connected with the four steam lines and the four feed-water lines hanging from the top in the upper pools. In addition, four containment condensers are mounted at the ceiling of the drywell, with the secondary side permanently open connected to pools above the containment, to condense the steam in the containment as soon as possible in the unlikely case. A boron poisoning system on top of the containment with a tank of Boron-10 is connected with the feed-water lines which serve as the second, redundant shut-down systems.

The unique feature of the Super LWR and Super fast reactor (FR) of Japan is that depressurization is used to provide a flow to cool the core under accident conditions (Oka et al., 2010). Turbine-driven auxiliary feed water systems and motor-driven low-pressure core injection (LPCI) system are applied on the cold-leg side to provide the function of keeping the coolant supply under abnormal conditions. Safety relief valves (SRVs) are applied on the hot-leg side to provide functions of keeping the coolant outlet open and mitigating over-pressurization. The SRVs also have a function of automatic depressurization to induce effective coolant flow. For reactor shutdown, the control rods and standby liquid control system (SLCS) are employed as in boiling water reactors.

SCWR plant concepts

Up till now, Canada, Euratom and Japan have successfully completed the development of their SCWR plant concepts, which were reviewed by international peers (Leung et al., 2018b). Fig. 8 shows the proposed SCWR plant concepts. Both Canada's and Euratom's core concepts are developed for the thermal spectrum. On the other hand, Japan has developed a thermal spectrum and a fast-spectrum cores using the same plant concept. China and the Russian Federation are continuing their development of their pressure-vessel type of core concepts. China is focusing on the thermal-spectrum core concept while the Russian Federation is working on a fast-spectrum core concept.

Improvements in economics, sustainability, safety and proliferation resistance for SCWRs

The GIF has set six technology goals for the Gen-IV nuclear reactor systems: improved economics, enhanced safety and reliability, improved sustainability, and enhanced proliferation resistance and physical protection (GIF, 2014). SCWRs have the potential of meeting most, if not all, these technology goals.

Economics

SCWRs are designed to operate at high pressures and high temperatures, which have led to increase in thermal efficiency. Compared with the current fleet of water-cooled reactors where the average plant efficiency is around 33%, the plant efficiency of SCWRs could achieve 43–49%. The increase in thermal efficiency would improve the fuel utilization, reduce waste heat and minimize spent fuel storage (Duffey and Leung, 2010).

In addition, the capital cost of SCWRs is reduced from the plant simplification and size reduction. The high operating temperature for SCWRs eliminates the need of inner circulation pumps, steam separators and dryers as in BWRs. On the other hand, the adoption of a direct thermal cycle for SCWRs eliminates the need of steam generators, pressurizer and main circulation pumps as in PWRs. Furthermore, the significant increase in enthalpy through the core and low mass flow rate of the system have led to reduction in sizing of equipment, piping, containment and reactor building. Economic analyses have shown reductions in capital cost by up to 20% for SCWRs compared to the Advanced BWRs (Schulenberg and Starflinger, 2012).

Fig. 8 SCWR plant concepts (Leung et al., 2018b).

Sustainability

Most thermal-spectrum SCWRs adopt the once-through uranium fuel cycle. As mentioned above, the improvement in thermal efficiency would improve the fuel utilization and enhance their sustainability. The introduction of the thorium fuel cycle for the Canadian SCWR would enhance further the sustainability as uranium fuel is no longer needed (Leung et al., 2012). Since thorium is fertile, the reactor-grade plutonium is used as the igniter and to breed U-233.

Fast-spectrum SCWRs (i.e., the Super FR of Japan and VVER-SCP of the Russian Federation) contain blanket regions in the fuel. The plutonium bred into these blanket regions (a breeding ratio of 1.021) contributes to the overall reactor power during its time in the core. Thermal-spectrum SCWRs do not rely on breeding fissile material in separate regions. However, plutonium is bred in the UO_2 fueled SCWRs and U-233 in the thorium fueled Canadian SCWR. The recycling of plutonium from the thermal and fast reactors is foreseen after prototype reactors have been demonstrated. The recycling of U-233 from the Canadian SCWR back into fresh fuel, eventually displacing plutonium as the starting fissile component, has been extensively studied in the context of other thorium-fueled heavy water reactors (Hyland et al., 2009).

Safety and reliability

The introduction of additional passive safety systems (such as the passive containment cooling system in the pressure-vessel type SCWR and the passive moderator-cooling system in the pressure-tube type SCWR) has improved the safety characteristics of SCWRs (Oka et al., 2010; Schulenberg and Starflinger, 2012; Leung et al., 2012). In addition, the avoidance of the critical heat flux phenomena due to non-existence of phase change of water at supercritical pressures has eliminated the sharp rise in cladding temperature in cases of the loss-of-reactivity-control or small-break loss-of-coolant accident scenarios. The stainless steel applied for fuel cladding reduces risks of hydrogen explosion. Moreover, simplification of systems and elimination of components, such as steam generators and primary heat-transport pumps in PWRs or recirculation pumps and steam separator and dryers in BWRs greatly reduce the possibilities of system and equipment failures causing abnormal conditions. That would enhance the reliability of the SCWR plants.

Deterministic safety analyses have demonstrated the maintenance of cladding and fuel integrities for postulated accident scenarios. In addition, preliminary probabilistic safety analyses have shown reductions in core damage frequency for postulated accident scenarios in SCWRs compared to current fleet of nuclear reactor systems (Oka et al., 2010; Leung et al., 2012).

Proliferation resistance and physical protection

The proliferation resistance aspect of SCWRs with UO_2 fuel are similar to that of existing LWRs or CANDU reactors. Enhanced safeguards (such as virtual monitoring) have been incorporated in the plant design phase. The use of thorium fuel in the pressure-tube

type SCWR would improve the proliferation resistance characteristics as thorium is fertile, lesser amount of plutonium is produced, separating U-233 from U-238 is difficult, and the production of U-232 (a high gamma-emitting decay chain) deters extraction (Leung et al., 2012).

The reduction in SCWR plant footprint and sizes of containment and reactor building due to the elimination of components required in PWRs or BWRs would reduce the areas to be monitored and surveyed enhancing the physical protection aspect.

Challenges

Technical challenges were encountered over the course of the SCWR development. These challenges arose mainly from the high core outlet temperature and the high enthalpy rise of the coolant in the core compared to current water-cooled reactors. Key challenges have been identified in six main technology areas.

System design and neutronic

- The SCWR core concepts are more complex than those of conventional LWRs to accommodate the high enthalpy rise. Multiple flow passes have been introduced to mitigate this challenge. This requires an internal separation of regions in the core further complicating the design and manufacturing processes.
- Water at high temperatures has lower moderation than that at low temperatures. Separate flow passes within the fuel assembly are needed to increase the moderation. This has increased the complexity of the fuel assembly design.

Materials and chemistry

- Materials for most core components have been identified. However, the selection of a cladding material to withstand elevated temperatures (above 600 °C) remains a significant challenge (Guzonas et al., 2018). Several potential material candidates have been identified and additional R&D are required to confirm their applicability.
- Operation under SCW conditions introduces unique water chemistry challenges related to water radiolysis and corrosion product transport (Guzonas et al., 2018). A chemistry control strategy is required to mitigate these challenges on cladding-material selection and inspection and maintenance of components.

Thermal-hydraulics and safety

- The large coolant density variation within the core could lead to instability and subsequently large neutronic variation and high fuel cladding temperature.
- Proven safety systems known from advanced boiling water reactors have been adopted in SCWR plant concepts. Due to high operating pressures and low water inventory, the pressure decreasing time scale in SCWR is shorter for LOCAs than that in conventional LWRs. This poses increased demand for the engineered safety systems.

Future plans

Development and experimental plans have been established to improve the current conceptual SCWR designs and address identified challenges. All designers recognize that a collaborative effort is required to fulfill these plans. The ultimate goal from this collaboration is to complete the design and operation of a demonstration plant. Specific areas of interest are summarized below.

System designs

Designers in Canada, European Union and Japan have completed their conceptual design of the thermal-spectrum SCWR plant (Leung et al., 2018b). Those in China are focusing on completing their reference design of the thermal-spectrum SCWR plant (i.e., CSR1000), and are not planning to pursue the mix-spectrum SCWR concept. Designers in Japan and the Russian Federation are continuing their work on the fast-spectrum SCWR concepts.

The modular design of SCWR can accommodate sizing for local deployment needs. Small modular SCWR concepts are being developed for electricity generation from 15 to 350 MW (Yetisir et al., 2012; Novikova and Bogoslovskaya, 2017).

Materials and chemistry

Material research aims to finalize the selection for fuel cladding. Testing of material candidates will be continued to improve the understanding of their corrosion and cracking behaviors. A round-robin testing of stress-corrosion cracking for selected material candidates has been scheduled. Research organizations from China, Canada and European Union will participate in the exercise.

Testing of a small-scale fuel assembly in a research reactor is considered a mandatory step before the construction of a prototype SCWR. A material test loop capable of operating with supercritical-pressure water has recently been constructed at Centrum Vyzkumu Rez (CVR) in Czech Republic. It has provided ample experience on design, construction and installation of a supercritical-water facility. The loop is undergoing the licensing process and will come online shortly.

Neutronics

Reactor physics analyses have been performed using analytical tools developed for light water and heavy-water reactors. Nuclear data are available for high-temperature conditions but not at relevant pressures. Previous analyses concluded the effect of pressure on reactor physics parameters is small. However, nuclear data would be required for the construction of the demonstration SCWR plant.

Safety system design

An integral test facility is required to demonstrate the effectiveness of the safety system design in SCWRs. Design and construction of a full-scale integral facility are time consuming and costly. A scaled-down system could be applicable to examine the phenomena and minimize the time and cost. Scaling analyses have been performed for major components in the safety system to confirm feasibility. An integral analysis is being carried out to quantify the appropriate scaling factor using a safety analytical tool.

Full scale fuel bundle test

Thermal-hydraulics experiments were performed using simple channels (such as tubes and annuli) and bundle subassemblies with three, four or seven rods. Licensing of the demonstration unit and a full-scale SCWR plant would require thermal-hydraulics data for full-scale fuel assemblies. Significant expansion of current facilities is required for licensing purposes.

A demonstration of SCWR plant

A demonstration SCWR plant is required before deployment. The design and construction of the demonstration plant require a strong collaborative effort among international community.

Summary

SCWRs are the natural evolution of the current water-cooled reactor technology (i.e., PWRs, BWRs or HWRs), which have accumulated over 50 years of design and operation experience. While improving economic is the main objective for the development, SCWRs have the potential of meeting all GIF technology goals of improving economics, safety and reliability, sustainability, and proliferation resistance and physical protection.

Seven SCWR core concepts have been developed covering thermal and fast spectra in pressure vessel and pressure-tube configurations. Fuel assembly concepts were established specifically for these SCWR cores. Most of these concepts were based on the traditional uranium fuel while the one for the pressure-tube type SCWR adopted the thorium fuel. Three groups of developers from Canada, European Union and Japan have also completed their plant concepts. Those from China and the Russian Federation are working on their concepts.

Despite of the success in completing the SCWR core and fuel concepts, technical challenges attributing to the high cladding temperature were encountered. Mitigation strategies of these challenges have been established with specific work planned.

Brief history and current status of LWRs

Light water-cooled reactors are by far the most mature nuclear technology, delivering reliable power since the first commercial pressurized water reactor (PWR) began its operation in Shippingport, PA in 1957. Commercialization of PWR technology was a direct consequence of the successes of the US Naval Reactors program, borrowing many technology features identified by the program, such as zirconium-based cladding, UO_2 fuel and pressurized water as a coolant. Generating steam directly in the reactor core was originally in question due to core stability concerns. However, the series of BORAX experiments in the 1950s and 1960s showed that boiling water reactors (BWRs) are also feasible, leading to the progressively improving line of BWR designs. BWRs offer the advantages of simpler plant layout with no need for steam generators as in PWRs (although earlier designs did have them), lower operating pressure, and a somewhat more flexible load following capability. The main drawback of BWRs is the presence of slightly activated water circulating through the turbine and the rest of the power plant. Overall, the economics of PWRs and BWRs have proven to be comparable, and so are the safety characteristics of modern designs.

LWRs have undergone significant evolution since the early days of nuclear power. Advanced cladding alloys, experience with UO_2 fuel and its manufacturing process, as well as improved understanding, monitoring and control of the coolant water chemistry, have led to substantial increases in fuel burnup (up to 60 MWd/kg), increases in operating cycle length between refueling outages (up to 24 months), improved capacity factors, and continual reductions in fuel failure and radiation doses to plant personnel in modern LWRs. Many existing LWRs were successfully re-licensed, allowing them to operate at higher than their originally designed power, or for longer than their original operating lifetime, or both. The successful power uprates range from a few percent to up to 20% of the original power capacity; these were enabled by improved instrumentation (thus, lower measurement uncertainties of the plant parameters), better understanding of critical components' degradation mechanisms, and some equipment refurbishment or replacement. In the United States, many LWRs built in the 1970s and 1980s have successfully gained an operating license extension from their original 40–60 years. At the time of writing, two PWR units at Turkey Point, Florida, and two BWR units at Peach Bottom, Pennsylvania, have been granted their operating license extension to 80 years.

Direct descendants of early prototypes, such as Shippingport and the BORAX experiments, resulted in what is known as the first generation of LWRs. These were relatively low power (< 1000 MW electric), relatively inefficient and somewhat complex designs. This was due to the limited experience and relatively large uncertainties, which therefore required large engineering safety margins. These reactors, however, shared most technological features, layouts, and materials choices with the modern-day LWRs. With better understanding of operational issues and component manufacturing, as well as construction techniques, the efficiency and size of reactors substantially increased, giving rise to the Generation-II LWRs, which also had improved safety features. The majority of LWRs operating today are of Generation-II. The most significant changes were associated with the growing emphasis on safety following the accidents at Three Mile Island in 1979 and Chernobyl in 1986. The main LWR design challenge with regards to safety is related to satisfying two conflicting objectives: effective cooling of the core in all expected accident conditions and containment of radioactive fission products (FP) should the core integrity be compromised. Meeting the latter objective requires designing ever more robust and tightly sealed containment structures, while the former requires efficient ways of removing the stored energy from within the containment into the environment (i.e., to the ultimate heat sink).

Originally, PWR designers opted for large containment volumes, sometimes with integrated intermediate heat sinks such as an “ice condenser” that could partially absorb the energy released in an accident. In addition, cooling water sprays would scrub the containment atmosphere of FPs and condense the steam, relieving the containment pressure and reducing the probability of leakage.

BWR designers introduced the concept of a suppression pool as an intermediate heat sink within the containment, temporarily absorbing some of the energy generated by the core in an accident, allowing the containment to be very compact. Blowing potentially radioactive steam from the reactor pressure vessel (RPV) through the suppression pool also allows partial removal of fission products and condensation of the steam—provided the water in the suppression pool remains below saturation temperature.

Another challenge associated with safety of LWRs is that the cooling water must be pressurized to achieve a reasonably high temperature of heat addition to the power cycle and, therefore, reasonable thermodynamic efficiency of power conversion. If the integrity of the cooling circuit were compromised, the loss of coolant would be very rapid and would need to be counteracted by makeup water injection. This is typically accomplished by motor-driven pumps, which require an alternative source of power such as Emergency Diesel Generators (EDGs). In BWRs, the task of reflooding the core with water was further complicated by the presence of coolant recirculation pumps, which control the coolant flow through the core and had to handle the entire recirculation flow rate. Recirculation pumps in early BWR designs required piping connections to the RPV below the core. Therefore, reflooding the core in case of a large break of one of these pipes would be impossible. Later BWR designs featured a larger suppression pool and the introduction of jet-pumps, which substantially reduced the flow rate external to the RPV and allowed the lowest level of large pipe penetrations to be at about two-thirds of the core height level.

Nearly all LWRs being built today are of Generation-III, which offer further improvement in efficiency and attempt to address the shortcomings of the previous Generation-II designs. In terms of economics, the prevailing trend until recently was to increase the power output of reactor units in pursuit of “economies of scale,” with the largest design currently on the market being the European (or Evolutionary) Pressurized water Reactor (EPR), with electric power output of nearly 1700 MW. This trend, however, led to an increase in complexity of the designs and challenges with the management of construction projects. The latest experience with construction delays has raised concerns over the viability of large reactors. This led the proposal of an alternative strategy of modular construction of smaller units in factories. Small Modular Reactors—SMRs, discussed in detail in [Reitsma \(2021\)](#) and [Ingersoll \(2021\)](#), can then be transported and assembled on-site with minimal construction effort.

In terms of safety, Generation-III LWR designs have many commonalities. For example, both PWR and BWR designers recognized the benefits of having a large water tank in close proximity of the core (the large suppression pool in BWRs and the In-containment Refueling Water Storage Tank, IRWST, in PWRs), which can serve as temporary heat sinks, allowing fast but controlled de-pressurization of the core and serving as a source of makeup cooling water. To improve reliability and reduce costs through simplification, modern LWRs increasingly rely on natural phenomena—such as gravity-driven flow or natural convection of coolant and/or air—to accomplish their safety functions, rather than requiring backup power from EDGs. Safety systems of some designs are entirely passive (e.g. AP-1000—a PWR designed by Westinghouse and ESBWR—Evolutionary Simplified BWR designed by GE-Hitachi) or include a combination of passive and active systems: active, when a fast response time is desirable, and passive, where its use leads to improved reliability of the design and requires long periods of operation (e.g. APR-1400, VVER-1200, ABWR). These latest designs are often referred to as Generation-III+ reactors. Jet-pumps have been replaced by recirculation pumps which are fully integrated into the RPV in the GE-Hitachi ABWR with no pipe connections at the core level—a feature successfully used in earlier ABB and Siemens BWR plants. GE-Hitachi has gone even further and introduced fully natural circulation-driven flow in their ESBWR design, which, as mentioned earlier, also offers fully passive safety systems to cope with all design basis accidents.

In summary, Generation-III/III+ LWRs have made unprecedented advances in the efficiency and reliability of operation, service life, and in safety, reducing the probability of core damage by up to two orders of magnitude compared to Generation-II LWRs. However, a number of frequently voiced reproaches remain to be addressed and have resulted in a vibrant research field, occupied by academics, national labs, reactor designers as well as nuclear plant operators. Have the LWRs reached their potential or can they do more or do better? The remainder of this article will present an overview of advanced LWR concepts aiming to address some of these challenges.

Challenges of the current fleet

In 2001, an international forum of experts was tasked with developing criteria for assessing the societal attractiveness of future nuclear energy systems, screening advanced reactor concepts against these criteria, and identifying those worthy of further development through international collaboration—also known as the Generation IV International Forum (see [Stanculescu, 2021](#)). The basic requirement was that Gen-IV reactors should offer substantial advantages over Gen-III LWRs in terms of economics, safety and security, sustainability of resources, and waste management. Therefore, existing LWR design challenges can be grouped in accordance with these themes.

Economics

The practically achievable thermodynamic efficiency of power conversion in LWRs is relatively low, on the order of 33%, which is substantially less than that of modern Combined Cycle Gas Turbines (> 60%) or Supercritical Coal power plants (> 50%). The efficiency of LWR power cycles is limited by the maximum coolant temperature (around 300 °C) and pressure (about 15 MPa in PWRs). These operating conditions are already pushing the boundaries of state-of-the-art manufacturing of large reactor components, such as steam generators and RPVs.

Furthermore, the cost of LWR-generated electricity is largely determined by the construction (capital) cost of the plant with only a minor contribution from operating costs. It is therefore desirable to reduce the capital costs as much as possible in order to achieve favorable economics. Capital costs strongly correlate with the reactor core power density: the more compact the core is for a given reactor power output, the smaller the expenditure is on many of the plant components. Modern PWR power densities are hard to challenge; it is not a coincidence that this reactor type is preferred in most naval propulsion applications, where compactness is the key feature. A substantial amount of R&D, as well as operational experience, has resulted in highly optimized LWR fuel and core designs, maximizing the core power output while meeting all safety criteria, seemingly leaving little room for further substantial improvements.

Sustainability of fuel resources

Current LWRs operate primarily in an “open” (or “once-through”) fuel cycle, in which freshly mined uranium is enriched, converted to UO₂, fabricated into fuel assemblies, and loaded into a core for generating nuclear heat. Following discharge from the core, the fuel is typically stored in cooling ponds and then dry cask storage for a number of years, pending ultimate disposal in geological formations suitable for immobilization of radioactive spent fuel constituents over time scales sufficient for their decay. This practice

allows only a small fraction ($< 1\%$) of the originally mined uranium's energy value to be utilized. For a typical LWR fuel with 4–5% initial enrichment, about 10 kg of natural uranium needs to be mined in order to produce 1 kg of enriched uranium. Furthermore, only about 5% of the enriched uranium loaded into the core will be fissioned, producing useful heat. This simple arithmetic suggests that 99.5% of the mined uranium's energy remains unused. The open cycle practice is presently the most economically preferred option because uranium is cheap and plentiful. The currently known reserves are sufficient to support even the most aggressive nuclear power expansion imaginable, at least until the end of the century. In addition, fuel costs constitute only a small fraction of the overall nuclear generation cost. Therefore, the cost of uranium is almost irrelevant to the economics of nuclear power. This approach, however, can be challenged on moral grounds: is it ethically justifiable for modern society to deprive future generations of a valuable energy source by following current practice?

Spent fuel contains non-negligible amount of fissile isotopes (mostly plutonium generated from neutron captures in U^{238} and remaining U^{235}) which can be recycled in existing LWRs as Mixed U–Pu Oxide (MOX) fuel—but only once—saving about 20% of natural uranium. This is a relatively well-established practice in many countries, most notably in France, but also in the United Kingdom, Germany, Belgium, Switzerland, Russia, and Japan. Further recycling is difficult because of the degradation of the plutonium isotopic vector, as it becomes less and less rich in fissile isotopes, as well as the increasing complexity of Pu recycling and MOX fuel fabrication. It has been argued, therefore, that in order to truly take advantage of the large energy content in spent LWR fuel (as well as in the depleted uranium tailings of the enrichment process), a completely different type of reactor with a fast neutron energy spectrum is needed, along with sophisticated spent fuel reprocessing and a recycling infrastructure to support them.

Safety

It has been noted that modern LWRs have come a long way in terms of improving their safety since the early days of the technology. The efforts to simplify the safety systems or eliminate certain fault scenarios continue and could result in substantial improvement in LWR economics. Two particularly high-impact issues are common to all LWRs, which led to complexity and high costs of safety systems: rapid loss of coolant in the case of a large-break in primary circuit piping, and rapid oxidation of zirconium cladding following the loss of coolant with an eventual loss of coolable geometry, preventing re-flooding of the core and leading to its further damage.

Weapons non-proliferation

Plutonium in spent nuclear fuel discharged from existing LWRs is not well-suited for use in nuclear weapons. It has a relatively small fraction (typically about 50%) of Pu^{239} , which is the most desirable isotope. Other plutonium isotopes significantly complicate weapon design because they have a high probability of spontaneous fission, which creates a high neutron background, leading to pre-initiation of an explosion and a substantial reduction in its explosive yield. Furthermore, Pu^{238} (constituting 2–3% of Pu in a typical spent LWR fuel) has a short half-life resulting in high heat generation, which would melt or cause spontaneous combustion of all generic high explosives used to compress the plutonium to achieve critical conditions. Although these complications may be viewed as a substantial deterrent against the use of Pu from spent LWR fuel for weapons proliferation, some argue that this possibility cannot be ruled out completely. Following discharge from the core, the Pu in spent fuel is self-protected from unauthorized diversion for several decades by the presence of highly radioactive fission products. However, after a few hundred years, once fission products have largely decayed, Pu could, in principle, be more easily diverted if access to a geological repository is gained by rogue states or terrorist groups. It is therefore desirable that the amount and attractiveness of weapons-usable material in commercial reactors spent fuel be minimized.

Spent fuel management

In spent nuclear fuel from LWRs, about 5% of the original uranium mass is converted into fission product isotopes. Many of these isotopes are highly radioactive. For this reason, they are also relatively quick to decay away, with the vast majority becoming stable isotopes in a few hundred years—a timeframe for which the environmental isolation of nuclear waste is a relatively simple engineering task. Other nuclides generated from multiple successive captures of neutrons in the original uranium isotopes—but without causing their fission—are known as trans-uranic elements (since they are positioned higher than uranium in the periodic table, e.g., neptunium, plutonium, americium, curium, etc.). Plutonium isotopes constitute about 1% of typical irradiated LWR fuel, while the rest of the trans-uranic (TRU) nuclides collectively constitute only about 0.1% and are therefore known as Minor Actinides (MA). The majority of plutonium and MA isotopes are less radioactive than FPs, i.e., have longer half-lives. Additionally, some MAs have relatively high mobility in the environment. Therefore, they require environmental isolation for hundreds of thousands of years. Demonstrating the integrity of engineered barriers for nuclear waste packages over such time scales is a challenging task. Thus, a nuclear waste repository safety case relies on geology and historical analogues (e.g., studies of the natural nuclear reactor in Oklo, Gabon). Although licensing of geological waste repositories has been successful in several countries, in others, the process became prohibitively expensive financially or politically due to local public opposition (Metlay, 2021; Kadak 2021). Furthermore, a similar argument on the moral responsibility for the sustainable use of energy resources can also be made with regards to the nuclear waste legacy left to future generations. Therefore, reprocessing and recycling of all TRU isotopes until their complete fission has been proposed, not just to improve utilization of natural resources, but also to keep the long-lived radioactive isotopes away

from a geological repository. Numerous studies have shown that the task of transmuting the long-lived TRUs into short-lived FPs can be accomplished most efficiently by fast spectrum Gen-IV reactors.

Emerging solutions

High operating temperature

One way of improving the economics of LWRs is to increase the temperature of heat delivered to the power cycle. BWRs use a direct cycle, thus saving a small, but notable, loss of temperature difference required for heat transfer across a heat exchanger. A natural evolution of BWR designs would be to raise their pressure and temperature as much as technologically affordable. This direction of reasoning resulted in the development of the super-critical water-cooled reactor (SCWR) concept discussed in detail in [Zhang et al. \(2021\)](#).

Increasing the operating pressure and coolant temperature may not be feasible due to manufacturing challenges and the availability of high-temperature corrosion-resistant materials for SCWR core components. An alternative solution could be to keep the operating pressure within the conventional BWR range but allow super-heating of the saturated steam produced in the core. This task can be accomplished by dedicating certain regions of the core to be cooled by steam rather than a steam-water mixture, or by an external super-heater with a non-nuclear heat source. In fact, many early LWRs included either a fossil fuel (oil or coal)-fired or a nuclear superheater, which would increase the temperature of the saturated steam produced in other parts of the core and therefore increase the thermal efficiency of power conversion. These early attempts were only marginally successful. The most typical problems were with geometry distortion of the fuel in the superheater region of the core due to differential thermal expansion of materials or stress corrosion cracking. Additionally, drastic differences in neutron moderation in water- and steam-cooled regions of the core made control of the power distribution particularly challenging. Eventually, the complexities of having a superheater were not economically justifiable. Instead, increasing the pressure (and thus the temperature) of saturated steam produced in later generations of LWRs was found to be a more attractive design direction, with modern LWRs achieving higher power cycle efficiency with saturated steam than earlier designs with a superheater.

The idea of superheated steam has not been abandoned completely, however. Recent technology developments have led to the reemergence of interest in superheated steam reactors. These are:

- BWRs have accumulated vast operational experience with many issues of early designs being successfully resolved;
- Development of new cladding and structural materials along with understanding of mechanisms for their degradation;
- Successful operational record of superheated steam fossil plants;
- Substantial development effort in unconventional, high-performance fuel concepts such as annular, internally and externally-cooled fuel geometry ([Hejzlar and Kazimi, 2007](#)) discussed in some detail later in this article.

A recent study by [Ko \(2010\)](#) has combined the developments mentioned above and proposed a BWR with a double pass of coolant flow through a reactor core composed of annular fuel elements—the Annular-fueled Superheat Boiling Water Reactor (ASBWR). In the first pass, the cooling water flows along the outside surface of annular fuel elements, generating saturated steam. The steam is then diverted back into the core, this time, flowing inside the fuel annulus, picking up additional heat, which raises its temperature up to 520 °C before directing it to the steam plant. The ASBWR concept was shown to achieve power conversion efficiency in excess of 40%, which is considerably higher than existing LWRs, while having a core power density of about 50 W/cm³, which is comparable to conventional BWRs. The study, however, does not go beyond the basic feasibility of the concept and would require substantial follow-up research. As future work, the study suggests focusing on fuel performance modeling in such unusual conditions, as well as safety analysis. Assessment of the economic case is also needed to determine whether incremental revenues from more efficient power conversion would offset the incremental investment in more complicated core structures and less neutronically efficient fuel due to higher neutron absorption in the double cladding, which may also have to be made out of stainless steel rather than Zircalloy.

As discussed earlier, external superheaters may have more advantages. In addition to being simpler (the core operation can be decoupled from the superheater operation), it can potentially allow variation in the degree of the superheating or in the fraction of steam flow which is superheated. Such a mode of operation can extend the load following capabilities of nuclear power plants. This could be an extremely valuable feature for future low-carbon energy systems with a growing fraction of intermittent renewable energy generators. There are many options for energy sources to power the superheaters. For example, this could be a separate, independently-controlled nuclear core, cooled directly by steam or indirectly by another coolant (e.g. helium gas or molten salt), which then carries the heat from the core to the superheater. Alternatively, the source could be the exhaust of a conventional natural gas-powered turbine, which can provide heat at close to 600 °C, or direct combustion of natural gas or other fuels (such as hydrogen or ammonia) which can be synthesized using the energy produced by the system during periods of low electricity demand. Although the use of fossil fuels to superheat the nuclear generated steam will produce carbon emissions, these can be relatively low because it will be used only to meet the peak electricity demand and to raise the temperature of already hot steam, implying that the power conversion efficiency of fossil heat to electricity will be relatively high (comparable to a combined cycle gas turbine, [Wibisono and Shwageraus \(2016\)](#)). Finally, the superheater can be coupled to a heat storage system based, for example, on molten salt, and powered by a renewable energy source, such as a concentrated solar farm.

The idea of coupling LWRs with external superheaters has been recently explored in a series of studies by Wibisono and Schwageraus (2016) and Wibisono et al. (2019). It has been shown that a small BWR with an external superheater system can accommodate a range of power generation loads between 65% and 100% of total system power, while always operating the nuclear reactor core at its full power. Such a combined system can achieve a thermal efficiency of power conversion of about 40%, which is considerably higher than conventional LWRs.

High power density

Another approach for improving the economics of LWRs is to increase their power output for the same volume of the core and other components. An LWR's core power density is typically limited by the ability of cooling water to remove the heat produced in the core during reactor operation and under several limiting accident scenarios, such as a Large Break Loss of Coolant Accident. Degradation of fuel can occur as a result of multiple mechanisms under accident conditions. Broadly speaking, the most important of those are fuel melting and cladding failure due to excessive oxidation or strain at high temperatures. Increasing safety margins to any of these limiting phenomena could lead to cost savings due to either simplification (or complete elimination) of some safety systems, or the ability to operate at higher power while maintaining the same margins, or both. Therefore, the design strategies for achieving higher core power density aim at reducing the fuel and cladding temperatures at nominal and accident conditions, as well as searching for materials which can maintain high strength and oxidation resistance at high temperatures.

Since heat removal from fuel elements occurs through the fuel surface, increasing the fuel surface area would increase the heat removal capabilities for a given margin to fuel failure. A number of approaches have been suggested to increase the fuel surface area by transitioning from the standard cylindrical fuel pin geometry to alternative fuel shapes.

Annular fuel

In PWRs, one option is the aforementioned annular, internally- and externally-cooled fuel (Hejzlar and Kazimi, 2007). Cross-sectional views of the conventional and annular fuel pin geometries are compared in Fig. 1. By nearly doubling the fuel surface area, the surface heat flux is reduced proportionally, which also leads to a corresponding increase in the DNBR margin. By reducing the heat conduction path from fuel to coolant, the temperature difference across the thickness of the annular fuel pellet can be reduced by over a 1000 °C (Fig. 2). Cooler fuel increases the margin to melting and the amount of stored energy to deal with in loss of cooling accidents. Lower fuel temperature also leads to more robust fuel performance over irradiation, with less swelling and fission gas release. A number of neutron economy effects largely offset each other. For example, although there is a smaller Doppler reactivity decrement¹ because of the lower fuel ΔT between cold and hot full power core state, this is mostly offset by the larger magnitude of the Doppler Coefficient due to an increase in resonance captures in U^{238} and parasitic absorption in additional cladding material (Xu et al., 2007).

The initial testing of the concept by a consortium of US universities, industry, and national labs was very promising and drew interest from South Korea, where a parallel project was launched by KAERI (Koo et al., 2013). The R&D activities showed that a substantial power up-rate of existing PWRs of up to 50% is possible, while maintaining or improving the safety margins. The activities covered a wide range of topics including core physics, thermal-hydraulics, safety analyses, mechanical testing, manufacturing (including actual pellet and fuel pin fabrication) and economic assessments. Safety analyses performed by KAERI for 120% of nominal power cases suggest substantially improved fuel characteristics (lower fuel and cladding temperatures) in a range of typical design basis accidents, such as reactivity insertion and loss of coolant. Small-scale irradiation tests have also been performed and showed favorable performance of the fuel. Nevertheless, at the moment, there are no large-scale follow-up projects being carried out aiming at commercialization of annular fuel.

Fig. 1 Cross sectional view of cylindrical and annular fuel pin geometries. Hejzlar P, and Kazimi MS (2007). Annular fuel for high-power-density pressurized water reactors: motivation and overview. *Nuclear Technology* 160 (1).

¹Doppler Effect is an increase in neutron absorption in fuel nuclides with an increasing fuel temperature. It occurs due broadening of resonances in the fuel isotopes' absorption cross section as the fuel temperature increases. Therefore, hotter fuel will have lower reactivity.

Fig. 2 Comparison of radial temperature profiles at the core location with highest power (hot spot) produced per unit of fuel pin length (also known as linear heat generation rate expressed in kW/m) for solid and annular fuel. Hejzlar P, and Kazimi MS (2007). Annular fuel for high-power-density pressurized water reactors: motivation and overview. *Nuclear Technology* 160 (1).

Lightbridge fuel

Another fuel type with alternative geometry is being developed by Lightbridge Ltd. in cooperation with Framatome (Malone et al., 2012). In this case, the increase in fuel surface area is achieved by corrugating the edges of cylindrical cladding to form four fins, as shown in Fig. 3. This fuel shape is allegedly inspired by Russian marine propulsion fuel (Bays et al., 2012). Furthermore, the cruciform-shaped pin is twisted in order to provide coolant flow mixing, which enhances heat transfer and also removes the need for spacer grids, reducing the flow resistance. The Lightbridge fuel is in metallic form, which offers additional advantages due to its high thermal conductivity. Zirconium-niobium alloy cladding is metallurgically bonded with the fuel and deforms together with it to accommodate the irradiation swelling, which is claimed to be similar to conventional UO_2 fuel. A displacer in the center of the rod helps to lower the maximum fuel temperature. It is also made of zirconium alloy or may contain some form of burnable poison.

Similar to the annular fuel, a larger fuel surface area and low thermal resistance to heat transfer substantially reduce the Lightbridge fuel temperature and increase the MDNBR, allowing power up-rates while offering greater safety margins. The fuel being designed and tested by Enfission (a joint venture between Lightbridge and Framatome) is fully retrofittable into existing PWRs and would allow greater operational flexibility and a power uprate of up to 30%. A series of extensive irradiation testing has been performed in research reactors and the development team seems to be on track to complete the fuel qualification, although a detailed timeline for commercialization is not currently available.

A computational and thermal-hydraulic experimental study by Conboy et al. (2014) on power uprates of LWRs using similar helical cruciform fuel geometries have concluded that up to a 47% power uprate of PWRs is possible with such fuel, similar to what was found to be achievable in the annular fuel studies.

Larger number of pins

The simplest way of increasing the fuel surface area for the same fuel volume, however, is to reduce the fuel pin diameter and increase the number of pins in the core. Transitioning from conventional 17×17 pins PWR fuel assembly designs to 19×19 or more fuel pins per assembly will, of course, have some detrimental effects. These could include increased pressure drop and higher pumping power requirements, less mechanically rigid fuel—requiring a redesign or re-evaluation of fuel vibration limits on flow velocity—as well as an increased resonance capture rate due to increased surface area and parasitic absorption due to larger cladding volume. These effects can be potentially compensated by lower capital costs due to the higher core power density. This has been shown, for example, in an alternative tight-pitch core design of the IRIS reactor, proposed and jointly developed by an international consortium of Westinghouse with several universities (Saccheri et al., 2007).

Alternative fuel geometries, such as more numerous pins of smaller diameter, or annular or Lightbridge-type fuel, are somewhat less effective in allowing power uprates of BWRs than PWRs (Karahane et al., 2010; Ellis, 2006; Conboy et al., 2014). Increases in power density on the order of 20% appear to be possible for these fuel geometries. For annular fuel, the reduction in surface heat flux is offset by the requirement for greater coolant mass flux, which has a negative effect on the Critical Heat Flux² (CHF) in BWR conditions, as opposed to its beneficial effect in PWR conditions (Todreas and Kazimi, 2012). Higher coolant mass flux is necessary to compensate for the lack of mixing in the inner channels and the generally less uniform radial power distribution in BWR fuel assemblies.

A systematic re-evaluation of the BWR fuel design space has been performed by Shirvan and Kazimi (2013) with an objective of increasing the power density of conventional BWR cores while maintaining the same safety margins. The optimized design can achieve a 26% higher core power density as compared to the ABWR and has a 65% higher specific power.³ It uses 35% shorter fuel pins of smaller diameter arranged in 16×16 fuel assemblies. Higher power for the same CPR⁴ margin has been achieved through traditional strategies, namely, reducing the linear heat generation rate and coolant mass flux to compensate for slightly higher exit quality. The findings of this study are of significant importance because the proposed design uses conventional fuel geometry, materials, validated analysis tools as well as proven manufacturing techniques, effectively enabling a short path to licensing and commercialization. It appears that this study discovered a region in the BWR core design space which was previously overlooked by the designers because of the greater focus on fuel cycle efficiency rather than on capital costs. The latter, however, has evidently become substantially more important.

Hydride fuel

In LWRs, the coolant serves as the moderator. Therefore, the amount of water needs to be sufficient to satisfy both requirements, although some design compromises are often inevitable. In a recent study, for example, it has been proposed to use U–Zr hydride fuel in an attempt to reduce the coolant volume without compromising neutron moderation (Greenspan et al., 2009). U–Zr hydride has been used in research reactors for many decades operating at low, often nearly room, temperature. Its properties, however, in principle, do not necessarily preclude using it as a fuel form in LWRs, if the shortcomings are well-understood and properly addressed in fuel design (Olander et al., 2009). Metal hydrides typically have a thermal conductivity close to metals, which is much better than that of UO_2 and would limit the operating fuel temperatures to an acceptable level, even at typical LWR power densities. The study covered a wide design parameter space: both PWR and BWR conditions, square and triangular fuel pin lattices, conventional UO_2 and U–Zr hydride fuel, and, finally, “inverted” fuel pin geometry (a prismatic fuel block with coolant channels passing through it, which allows for larger fuel volume fractions than geometrically possible with conventional pins, even in triangular, tightly-packed lattice).

The study showed that a hydride fuel PWR core, with a tight triangular pitch and wire-wrap support, can achieve a sizable power density uprate of approximately 53% in comparison to conventional designs, provided about a factor of two higher coolant pressure drop across the core can be accommodated. In BWRs, the use of hydride fuel can eliminate the necessity for water rods, reducing heterogeneity of the fuel assembly and radial pin power peaking factors. The predicted power uprate possible through switching to hydride fuel in BWRs is insignificant if the core pressure drop were to be kept the same as in a conventional UO_2 core. Accommodating a 50% higher pressure drop would allow a power uprate of about 20% in comparison with modern 10×10 assembly designs. The most important technological uncertainty of hydride fuel use in LWRs remaining to be demonstrated is the compatibility of the fuel with Zr-based cladding materials and water coolant.

²Critical heat flux is the amount of heat transferred per unit area of cladding surface at which direct contact of boiling coolant with the cladding is no longer maintained. In PWR conditions, this typically occurs when vapor bubbles on the cladding surface either grow too fast or detach too slowly, resulting in their overcrowding and coalescence. In this case, they eventually form a continuous vapor film with poor heat transfer coefficient which leads to significant cladding temperature increase. In BWRs, direct contact of vapor with the cladding occurs when liquid film covering the fuel rods dries out up-stream the coolant flow in a channel with the same undesirable cladding temperature increase.

³Specific power is the amount of heat produced per unit mass of uranium in the fuel. It is typically measured in kW/kg.

⁴BWR cooling channel dry-out is a function of total power input into the channel rather than local heat flux as in PWRs. Therefore, BWR thermal margin is measured as a ratio of power input into the channel at which dry-out occurs to the actual operating channel power. It is known as the Critical Power Ratio (CPR), which must be sufficiently greater than unity to account for uncertainties and anticipated transients.

Improved thermal conductivity

Currently, the Critical Heat Flux (Departure from Nucleate Boiling Ratio in PWRs and Critical Power Ratio in BWRs) is more limiting to the achievable power density than fuel temperature in steady-state operation or in anticipated transients. Nevertheless, a greater thermal margin to fuel melting is generally welcomed because it can improve tolerance to accidents, such as loss of coolant. Similar to the use of metallic uranium alloys as in the Lightbridge design, fuel temperatures can also be reduced by using other fuel forms with substantially higher thermal conductivity than UO_2 , such as uranium silicide (U_3Si_2) or uranium nitride (UN). Enhanced thermal conductivity can also be obtained by admixing high-conductivity materials to UO_2 ceramic. Numerous additives have been proposed including beryllium oxide (BeO), silicon carbide (SiC), molybdenum, chromium oxide (Cr_2O_3), diamond, graphene, and others. The main idea here is to create a high-conductivity matrix in which fuel particles are dispersed. If the matrix network is not continuous, the enhancement of thermal conductivity is minimal or not observed at all. All additives, however, have their disadvantages. These include displacement of fuel, high neutron absorption, degradation of thermal properties with irradiation, chemical reactions with water, and complicated or costly manufacturing processes, to name a few. One of the leading candidates is BeO. It improves the thermal conductivity of UO_2 by approximately 10% for each percent of BeO added, with the conductivity of UO_2 essentially doubled at about 10% of BeO in the mixture (Garcia et al., 2017). The enhanced thermal conductivity alone (without changes in fuel pin geometry) cannot justify substantial power uprates to improve the economics of power plants. Instead, they are marketed as fuels with enhanced accident tolerance which can increase the safety margins in some accident scenarios and, therefore, lead to simplifications in the safety case and potential associated cost savings. Accident-tolerant fuels will be discussed further in a later section of this article.

Improved fuel utilization

Fuel utilization is typically measured in terms of the amount of energy generated per unit mass of fuel (fuel burnup) relative to the amount of natural uranium required to manufacture the fuel. In a typical LWR fuel, about two thirds of energy is produced from fissioning the original fissile atoms of U^{235} . The remainder is produced mostly from fissions in Pu^{239} generated as a result of neutron captures in fertile U^{238} . The amount of initial U^{235} represents the initial investment in the fuel (enrichment), while energy produced represents the return on that investment. It can be shown (Fei et al., 2014) that the levelized fuel cycle cost (Rothwell, 2021) is roughly proportional to the ratio of initial fuel enrichment to the fuel discharge burnup. The fuel cycle cost of LWR fuel is almost independent of enrichment because natural uranium, separative work, and attainable burnup all scale approximately linearly with enrichment. Therefore, fuel cycle costs and fuel utilization cannot be improved substantially by varying the enrichment but only by extending the fraction of energy produced from plutonium fissions, because their fractional contribution to total energy would increase with burnup. This can be accomplished by maximizing the rate of neutron captures in fertile ^{238}U (thus, maximizing the rate of fissile ^{239}Pu production) and the number of neutrons available for these fertile captures.

The first mechanism is related to the Conversion Ratio (CR), which is defined as the generation rate of new fissile material (essentially, the rate of neutron captures in ^{238}U) relative to the rate of fissile isotope disappearance (neutron absorption rate in ^{235}U and ^{239}Pu). If CR is greater than one, the system is said to be self-regenerating or a “breeder,” i.e., the system generates new fissile material faster than it consumes it. In a typical LWR, the average core CR lies within the range of 0.5–0.6.

The abundance of neutrons available for breeding is related to the η -factor, which, for a fissile isotope, represents the average number of neutrons released per neutron absorbed in that isotope. η -factors for the most relevant fissile isotopes as a function of the absorbed neutron energy are presented in Fig. 4.

As can be seen from the figure, the most abundant neutrons available for breeding are released as a result of fissions induced by high energy ($E > \sim 10^5$ eV) neutrons, making fast spectrum reactors particularly attractive with respect to achieving high fuel utilization. In thermal spectrum reactors ($E < 0.1$ eV), such as LWRs, the η -factors are only slightly greater than 2, which means that there are barely enough neutrons to sustain the chain reaction (at least one neutron is needed for criticality) and to compensate for the fissioned atom by producing a new one through fertile capture (at least one neutron is needed to sustain the population of fissile atoms). Since neutron losses to leakage and parasitic absorption in structural materials and coolant are inevitable in realistic systems, achieving self-sustainable breeding ($\text{CR} > 1$) in LWRs is extremely difficult in practice. Nevertheless, numerous concepts have been proposed to improve the conversion ratio, bringing it as close to unity as possible. A number of strategies are used in these concepts.

The excess reactivity of fresh LWR fuel is typically on the order of 0.3, i.e., it generates about 30% more neutrons than needed to sustain criticality (self-sustaining chain-reaction). This excess is offset by a combination of reactivity control means such as burnable poisons, soluble boron, or control rods. These excess neutrons are effectively lost and do not contribute to regeneration of fissile material through captures in ^{238}U because ^{238}U is not competitive enough for neutron absorption with much stronger absorbers, such as ^{235}U and reactivity control materials (e.g. boron or gadolinium). Therefore, at the beginning of fuel life, the excess of neutrons is high, but the CR is low. With irradiation, however, both the original ^{235}U and reactivity control poisons are depleted, diluted, or mechanically withdrawn, and the competitiveness of ^{238}U in terms of neutron absorption increases. Unfortunately, as the reactivity is lost, fewer excess neutrons are available for breeding, and a high CR leads to shortening of the fuel cycle and reductions in discharge fuel burnup. Therefore, the “holy grail” of high conversion LWR designs is to reverse this trend. At the beginning of life, it is desirable to have the CR as high as possible to maximize the capture of excess neutrons in ^{238}U , while it is desirable to reduce the CR towards the end of irradiation to increase the fuel reactivity, prolonging the burnup and allowing newly-bred fissile plutonium to contribute a larger fraction to total energy produced by the fuel.

Fig. 4 Average number of neutrons released per absorption in ^{233}U , ^{235}U , and ^{239}Pu .

Spectral shift

One of the approaches to achieve the favorable behavior described above is to vary the amount of neutron moderation along the burnup cycle. Reducing the moderation initially would make ^{235}U and reactivity control materials—which are mainly thermal neutron absorbers—comparatively less competitive with the primarily resonant absorber ^{238}U . Reduced moderation effectively shifts the energy spectrum of the neutron population away from thermal and towards the epi-thermal (resonant) energies. As a result, the CR is increased and the need for reactivity control is reduced.

The fractional change in the amount of ^{238}U atoms throughout the burnup cycle is relatively small. Therefore, without changing the level of moderation, captures in ^{238}U will contribute a relatively constant negative reactivity, shortening the achievable burnup. The overall CR will be improved somewhat, but the energy share of plutonium fissions could be extended if moderation is gradually increased with irradiation time. Shifting the neutron spectrum back towards thermal energies will increase the fuel reactivity by reducing the neutron absorption in ^{238}U and increasing the relative competitiveness of fissions in newly bred ^{239}Pu .

A certain amount of spectral shift is already a routine practice for currently-operating BWRs. Long-term reactivity control of BWRs is accomplished by gradual withdrawal of control rods. Smaller reactivity adjustments, however, can also be made by varying the speed of the coolant recirculation pumps. A higher coolant flow rate reduces the core average void fraction (fraction of water that boils), providing better moderation. Conversely, when the flow rate is low, the void fraction is high, leading to less moderation. Therefore, many BWRs tend to adjust their control rod positions such that, at the beginning of cycle, the flow rate is low, but then gradually increases with irradiation.

This effect can be amplified by using the Spectral Shift water-Rod (SSR) concept being developed by Hitachi (Kondo et al., 2010). In contrast to traditional BWR fuel assembly water rods (Hamon, 2021)—which are always filled with water during reactor operation—SSR has a U-shape with a large diameter ascending flow section and a small diameter descending flow section, with openings below and above the fuel pin support plate, respectively, at the bottom of the core. Neutron and photon energy deposition in the SSR water leads to boiling, while the pressure drop across the support plate allows for adjusting the water level in the SSR by varying the coolant flow rate. At low flow rates, the SSR would be mostly voided, while, at high flow rates, it would be filled with water.

Reduced moderation can be achieved in PWRs by a variety of means, the neutronic design implications of which are extensively discussed in Ronen (1989). Reducing the fuel pin lattice pitch increases the CR but leaves limited practical opportunities to adjust moderation throughout the cycle. It must be noted, however, that increasing the CR through reduced moderation can be a viable strategy if the newly generated fissile material can be extracted from the spent fuel and subsequently reused in a closed fuel cycle. This strategy will be briefly addressed later in this article, as well as in Shwageraus (2021) in more detail.

Instead of reducing the fuel lattice pitch, light water (H_2O) can be replaced with the same amount of heavy water (D_2O). Since heavy water is a less efficient moderator, this approach is somewhat equivalent to reduction in lattice pitch. Variable moderation can be achieved by gradually diluting the heavy water coolant with light water. This will obviously be hard to justify economically as heavy water would be a consumable commodity with considerable associated costs.

In order to reduce the loss of available neutrons to parasitic absorption in reactivity control materials, a number of options are available—some have been attempted and some are currently in use. Reactivity can be controlled by adjusting the liquid moderator level in pressure tube-type reactors e.g. the Plutonium Recycle Test Reactor in the United States, the Nuclear Power Demonstration (NDP) reactor in Canada (Mitchell III, 1964) and the Steam-Generating Heavy Water reactor in the United Kingdom (Cartwright,

1968). More recently, a pressure tube-type reactor concept has been proposed with double wall horizontal calandria channels (Rachamin et al., 2013). The space between the walls can be flooded for each channel separately, such that the neutron spectrum can be gradually softened during irradiation allowing to control the core reactivity.

Some reactors use continuous on-line refueling, such as the CANDU (Nichita, 2021) and British AGRs. LWRs use multiple fuel batch refueling—a strategy which makes use of excess neutrons in fresh fuel assemblies to generate power in adjacent subcritical fuel batches and allows achieving higher fuel burnup for the same initial enrichment.

The moderator can be initially displaced by mechanical means. For example, a high-conversion PWR concept has been developed by Framatome (Hittner et al., 1988). In the proposed design, hexagonal, tight-pitch fuel assemblies include guide tubes that can be occupied by either control rods or water displacement rods loaded with natural uranium. The water displacement rods are fully inserted initially. The CR, in this case, is high because of the reduced moderation and large amount of ^{238}U . With irradiation, the displacement rods are gradually withdrawn, improving the moderation and reducing the amount of ^{238}U capture, which compensates for the reactivity loss. This design can theoretically achieve CR very close to one, although it has never been implemented in practice. A similar concept is currently being developed for the next generation of Russian VVER reactors (Teplov et al., 2014).

The main challenge with increasing the CR of fresh fuel in LWRs is the large amount of initial fissile material and reactivity control poisons which compete for neutrons with ^{238}U . An alternative approach to increase the competitiveness of ^{238}U is to physically separate the fissile and fertile components of the fuel. This idea is known as the “seed-blanket” concept. The fissile material is concentrated initially in a seed region, which produces a large number of excess neutrons. These neutrons leak out of relatively small (on the order of one neutron mean free path) seed regions into the blanket fuel regions loaded mostly with fertile isotopes, where they are absorbed with high probability. The concept was pioneered by Alvin Radkowsky and implemented originally in the first commercial PWR at Shippingport, PA. The Shippingport core configuration was modified several times and the last one is known as the Light Water Breeder Reactor (LWBR) program (Atherton, 1987). This core consisted of seed fuel assemblies inserted into annular-shaped blanket fuel assemblies, loaded with ^{233}U and thorium, respectively. The reactivity control was achieved by mechanically moving the supercritical seed units in or out of blanket units. As can be observed from Fig. 4, ^{233}U has the largest number of neutrons released on average per neutron absorbed in the thermal energy range. This, in combination with exceptionally good neutron economy thanks to variable geometry reactivity control, allowed the core to achieve net breeding (i.e., $\text{CR} > 1$), which was then experimentally verified through post irradiation examination of LWBR spent fuel.

The idea of seed-blanket configurations has been recently revisited with the aim of achieving high CR, as well as other objectives discussed later in this article, such as improved proliferation resistance of spent LWR fuel.

In relation to the thorium fuel cycle, it has been shown that mixing enriched uranium and thorium homogeneously within LWR fuel does not provide any benefits with respect to uranium savings or extended burnup (Galperin et al., 2002). Heterogeneous, seed-blanket designs, on the other hand, can be optimized to achieve high CR and notably improve fuel utilization in a once-through fuel cycle, or achieve near-breeding performance in cores intended for multi-recycling of fissile material. Spatial separation can be implemented on a micro-scale, e.g., fissile and fertile regions within a single fuel pellet (Shwageraus et al., 2004), or macro-scale, on the order of full fuel assembly size (Baldova et al., 2016; Kotlyar and Shwageraus, 2012). Heterogeneity can be in the radial (groups of pins or full assemblies) or axial (alternating axial fuel zones) directions, or both. One of the major challenges of seed-blanket designs is accommodating significant power peaks resulting from drastic differences in fissile fuel loading in different assembly regions. Coolant flow can, in principle, be distributed in proportion to the power expected to be generated in different regions. However, this is still difficult to achieve without negatively impacting the core average power density. The addition of even small amounts of fissile material to the blanket in order to flatten the power distribution reduces the CR significantly.

All the methods applied to an LWR once-through fuel cycle described so far in this section are capable of only relatively modest improvement in fuel utilization—on the order of 20–30%. An order of magnitude greater improvements can be achieved if a high CR or even a breeder core is combined with a closed fuel cycle infrastructure. Multiple irradiated fuel components can be recycled. These include the remaining uranium with depleted fissile content, plutonium with a high fraction of fissile isotopes, as well as minor actinides, some of which are fissile and, thus, have high energy value. Recycling of spent fuel is discussed in more detail in Shwageraus (2021).

At the moment, one of the most advanced LWR concepts, under active development for the past 20 years, is the Resource-renewable Boiling Water Reactor or RBWR (Takeda et al., 1995; Hino et al., 2015).

The concept uses a tight-pitch hexagonal fuel lattice as well as a higher-than-conventional BWR void fraction to achieve reduced moderation and increase the CR. Furthermore, spatial separation of fissile and fertile fuel zones in the axial direction is employed. In addition to improving the CR, heterogeneous arrangement serves the purpose of achieving negative void reactivity feedback.

In reduced moderation, plutonium-driven lattices, the coolant density coefficient of reactivity can be positive, especially for fuels with high plutonium content (Aniel et al., 1997). The positive void reactivity effect can be counteracted by a negative neutron leakage effect. With loss of moderation due to voiding, the probability of neutron loss due to leakage increases, which reduces the core reactivity. The leakage effect can be amplified by changing the core aspect ratio to increase the surface area through which the neutrons can leak. For large cores, however, this strategy has limited benefit because the fraction of leaking neutrons is relatively small and because, after all, neutrons are needed for sustaining the core criticality for as long as possible to achieve favorable economics and for efficient breeding of new fissile material. Neutrons lost to leakage would negatively affect both.

In the RBWR, the core is much shorter than, for example, in the ABWR (1.3 vs. 3.8 m), while having the same equivalent diameter, making it significantly more leaky. The fuel is arranged in an axially heterogeneous “parfait”-like core, where fissile (seed)

layers—loaded with MOX fuel—are sandwiched between fertile layers—loaded with natural or depleted uranium—as schematically shown in Fig. 5. Upon an increase in the core void fraction resulting in spectrum hardening, the neutron leakage from fissile into fertile zones will increase, reducing the core reactivity. The leaking neutrons in this case are not lost, but are absorbed in the fertile blankets.

The RBWR concept can be applied not only in the context of fuel multi-recycling to improve its utilization manyfold, but also for efficient burning of Pu and MA if this is chosen to be the fuel cycle objective. Furthermore, the RBWR can operate in a closed U^{233} –Th fuel cycle with some modifications to the core design (Greenspan et al., 2015).

The concept is particularly attractive because it essentially allows for achieving many of the Gen-IV goals while using well-established LWR reactor technology. This is, of course, provided that the closed fuel cycle infrastructure is available and can operate cost-effectively. RBWR core modifications (for the U–Pu or thorium fuel cycles, breeder or actinide burner) are designed to fit into an ABWR pressure vessel, and have the same operating characteristics—such as system pressure, feed water flow rate and total power—so that the conventional ABWR power plant can be used. The RBWR development and design studies have been mostly theoretical, supported by experiments in key areas, such as boiling thermal-hydraulics in tight lattices and axially heterogeneous heat fluxes. However, there are plans to establish an experimental program based on the findings of the studies performed so far.

Simplified safety case

The challenges of LWRs described earlier in this article have been known for many years and recognized by the industry—reactor designers, operators, and regulators. Numerous attempts have been made to address these issues so that the safety case can be simplified, reducing the costs of nuclear energy and improving public acceptance. The proposed new features that could achieve the simpler safety case objective can be broadly grouped into the following categories:

- Reliance on passive mechanisms to assure reactor shutdown and residual heat removal without the need for off-site power. This can be accomplished through natural convection, gravity-driven flows, and large quantities of cooling water stored in close proximity to the core, so that availability of a heat sink is assured for prolonged periods of time. Natural circulation of coolant could be employed only for removing the decay heat or used also in nominal operation at full power. Electric batteries for instrumentation and valve actuation, as well as compressed gas energy storage for fast, high-pressure, coolant injection may still be needed, but the requirement for Emergency Diesel Generators to move the decay heat to the ultimate heat sink will not be necessary.
- Integral design of a PWR Nuclear Steam Supply System (NSSS), in which steam generators are located inside the reactor pressure vessel. This allows eliminating a whole family of faults associated with breaking of the primary coolant circuit piping and a subsequent loss of coolant.
- New fuel forms and cladding materials which can survive the loss of core cooling for prolonged periods of time without losing their integrity and releasing fission products.

One of the earlier concepts worth mentioning is PIUS—Process Inherent Ultimate Safety (Hannerz, 1987). It was under development in the 1970s as part of a collaboration between Sweden and Finland to develop an inherently safe LWR called SECURE for district heating and electric power generation. Part of the PIUS primary loop containing the core is submerged in a large pool of cold borated water. The loop has openings into the pool below and above the core but, under normal operation, the primary water does not mix with the pool water. The mixing is prevented by so-called density locks (interfaces between cold and hot water), which are kept in place if the primary loop temperatures and flow rate are within the normal operation window. In case of power loss to the

Fig. 5 Schematic view of an RBWR fuel assembly. Courtesy Hitachi 2020 used with permission.

primary coolant circulation pumps, a natural circulation is passively established between the core and the pool water. The concept can also be extended to BWRs (Forsberg, 1986).

Another concept is an early version of an integral PWR called SIR—Safe Integral Reactor (Matzie et al., 1992). It was developed as a collaboration between ABB Combustion Engineering, Rolls-Royce, Stone & Webster and AEA Technology. Apart from placing all the primary coolant loop components into a single pressure vessel to eliminate large pipe break loss of coolant accidents, the design also featured a compact pressure suppression containment—a feature previously common only to BWRs. Safety was achieved by primarily passive means through natural convection and without the need for EDGs.

Many of the features mentioned above have already been adopted in current Gen-III+ designs such as the AP-1000 and ESBWR. Both designs benefit from fast, automatic depressurization, passive decay heat removal by natural convection, and a large volume of cooling water near the core. The ESBWR also has no coolant pumps to force the coolant flow through the core in normal operation, relying instead on natural convection. Due to simplification and passive safety features, both designs claim significant reductions in the number of needed pumps, piping, and valves.

The first four AP-1000 power plants have recently been brought online in China, and two more are under construction in the United States at the time of writing. The reported financial, regulatory, manufacturing, and project management difficulties of the first units can be attributed to the construction of first-of-a-kind plants. Therefore, it would be somewhat premature to speculate whether the promise of cost reduction due to the simplification of safety systems has been realized. There are no firm ESBWR orders at the moment, but the design is mature, gaining the US NRC certification in 2014. Several sites in the US either applied or were already issued a combined Construction and Operating License (COL).

Simplification of the safety case is likely to be easier to achieve if the physical size of the reactor is small. It is easier to accommodate large quantities of cooling water, substantially increasing the volumes of primary and emergency cooling systems per unit area of fuel to be cooled. It is also possible to submerge the entire primary vessel in a large pool, serving as a heat sink, or integrate all the primary circuit components into a pressure vessel. Therefore, multiple Small Modular Reactor (SMR) designs taking advantage of the above features have been proposed and are currently under active development. Further chapters (Reitsma, 2021; Ingersoll, 2021) dedicated to SMRs describe their designs in more detail.

Integral designs of large PWRs do not have quite the same level of maturity as some of the SMRs. A conceptual design of a large integral PWR has recently been studied by a consortium of US universities, Westinghouse, and a number of international partners. The Integral Inherently Safe—I²S-LWR has 1GWe power output (Memmott et al., 2017). It is extremely challenging to fit all the primary components into the RPV. Therefore, integral, compact heat exchangers are used to transfer heat to the secondary pressurized water, which is then directed into “flashing drums” where the pressure is reduced, and a large fraction of water is flashed into steam. The remaining water is pressurized again by an external pump and directed back into the RPV. The decay heat removal from the I²S-LWR is fully passive and accomplished through dedicated natural circulation heat exchangers also located in the RPV. The core has 121 fuel assemblies with a larger than conventional number of fuel pins (19×19), providing a large cooling surface area and allowing the I²S to achieve about 20% higher power density than in conventional PWRs. The fuel is uranium silicide (U_3Si_2) which has a higher heavy metal density and thermal conductivity than UO_2 .

Advanced fuels with high thermal conductivity and large surface area have already been mentioned in relation to increasing the core power density and, thus, achieving better economics. In this section, it is worth mentioning advanced cladding materials also, which can maintain their strength and resist oxidation at high temperatures. Since the Fukushima accident in 2011, a search for more oxidation-resistant cladding materials became a particularly active area of research. Traditional Zr-alloy-based cladding poses a number of safety challenges: it loses its mechanical strength dramatically when heated beyond approximately 700 °C; it exothermically reacts with steam at temperatures above 1200 °C, generating heat which is comparable, or even up to an order of magnitude higher than decay heat a few hours after LOCA initiation; hydrogen gas is generated during oxidation which can accumulate and combust with an additional large and rapid energy release.

A number of options are currently being pursued as advanced cladding materials for Accident-Tolerant Fuel (ATF) with various degrees of technological maturity (Terrani, 2018). The simplest and the most near-term solution is oxidation resistant coating (e.g. chromium) of traditional Zr-based cladding. Fuel qualification work on the coated cladding is well on the way by many fuel vendors. The first commercial products are expected to be available within the next few years. This concept, however, does not resolve the problem of having large amounts of Zr in LWR cores which would still represent a significant source of stored energy and which can be released if high temperature water does get in contact with Zr.

A somewhat more advanced concept is Fe-Cr-Al alloys. They have a similarly low oxidation rate as Zr-coatings. However, in this case, the exothermal Zr oxidation energy source is eliminated entirely. The cladding is also stronger and can maintain its integrity in relevant accident scenarios for up to several hours longer. High neutron absorption compared to Zr is a disadvantage and would require a slight enrichment increase to compensate.

A possible “gamechanger” technology is based on SiC/SiC composite materials. Fibers of SiC can be weaved into a desired tubular shape and infiltrated with crystalline SiC, forming an air-tight matrix. It can then be combined with either additional monolithic SiC layers or metallic layers, so that the hybrid material would have an optimal combination of all the desirable properties. SiC/SiC composites have shown high strength and good oxidation resistance under variety of conditions. SiC also has low neutron absorption and it is a good moderator. If the behavior of such materials is well understood and manufacturing techniques mastered, the ceramic composite cladding can potentially survive without cooling for sufficiently long periods of time to convince regulators around the world that the reliability and redundancy requirements on LOCA protection equipment can be relaxed. Before these advantages can be realized, however, further development is still required in areas such as radiation-resistant bonding of cladding

components, understanding of micro-crack formation mechanisms and migration of fission products through them, as well as the development of fracture mechanics codes and standards necessary for qualification of ceramic cladding materials—these currently exist only for metals (Terrani, 2018).

SiC has also been successfully used as the coating of small (about 0.5 mm in diameter) spherical UO_2 kernels. These are known as TRISO fuel particles. The particles can be either embedded into graphite, 6 cm diameter spheres (pebbles), or pressed into cylindrical rodlets (compacts), for use in gas- and salt-cooled high temperature reactors. TRISO particles have been shown to be incredibly robust, maintaining integrity of the coatings and retention of fission products at up to 1600 °C (IAEA, 2010).

TRISO particles embedded into SiC matrix pellets can be loaded into a SiC composite cladding tube. An additional layer of protection (particle coating plus cladding tube) and elimination of many undesirable and difficult to predict fuel irradiation effects, such as cracking, swelling and fission gas release, can provide even further accident tolerance. This concept is known as Fully Ceramic Microencapsulated (FCM) fuel (Terrani et al., 2012). Although technologically feasible, manufacturing of such fuel is likely to be costly. An additional complication is much lower fuel heavy metal density because fuel is displaced by the TRISO coatings and the matrix. The enrichment required to compensate for such a loss of heavy metal loading can be as high as 19% (Shapiro and Frantoni, 2016), which would further escalate the costs of FCM fuel manufacturing. However, these costs may well be offset by the safety case simplification as alluded to previously.

Non-power applications of LWRs

Expanding a nuclear energy contribution to the decarbonization of the world economy is currently a matter of urgency. It is therefore highly desirable for nuclear reactors to offer other energy products in addition to the generation of electricity. Non-power applications also represent a potentially attractive commercial opportunity to improve the economics of nuclear power. A number of such non-power applications are possible. Many have been hypothesized—some of them became mature designs—others have actually been constructed and operated commercially.

LWRs operate at relatively low temperatures—around 300 °C. This feature somewhat limits the extent of non-power applications. Energy intensive industrial processes typically require much higher temperatures, achievable only in gas-cooled or other Gen-IV reactors (Stanculescu, 2021). This is also the case for high-efficiency hydrogen generation methods. At room temperature, electrolysis of water is possible, but is much less efficient and therefore expensive. That being said, such a hydrogen production plant could be completely decoupled from the nuclear power plant, which would only supply the electricity. A hydrogen plant can be thermally coupled to an LWR (Frick et al., 2019). In this case, the low-grade nuclear heat can be topped up with resistive heating by electricity or other means and then used in a much more efficient high-temperature solid oxide electrolyzer cell (SOEC). However, the fractional contribution of low-grade nuclear heat to the total energy consumed in hydrogen generation is modest (on the order of 10%). A number of studies have been conducted around the world on using existing LWRs for hydrogen production employing these strategies and several reactor operating companies expressed interest in pilot projects. The biggest technical challenge at the moment is degradation of the electrolyzer cell electrodes, which is currently a topic of particularly active research.

The most attractive commercial opportunities for using relatively low-grade LWR heat efficiently lie in sea water desalination and district heating. Both have been proven successful with several operating commercial prototypes. Many countries face a scarcity of water resources or envisage such scarcity in the future. However, currently only a small proportion of the world desalination capacity is met by nuclear power. A similar situation exists with district heating applications.

Multiple options for coupling nuclear and desalination plants are available. Reverse Osmosis (RO) methods require only electricity, although the efficiency of the process can be boosted by about 10–15% if feed water is preheated. This is a mature, widely-deployed technology.

Part of the nuclear-generated steam can be diverted at various stages of power turbines and used directly to drive thermal desalination processes, such as multi-stage flash (MSF) and multi-effect distillation (MED). The latter was shown to be somewhat more cost-effective (IAEA, 2007). Thermal processes also have an advantage of producing an order of magnitude lower salinity product than RO. Thermal processes can be combined with RO and offer greater flexibility for the plant to follow the variations in electricity demand, which can be particularly attractive in electricity grids with a high penetration of intermittent renewable energy generators.

Many northern countries have domestic heating as a large fraction of their energy consumption. Some have well-developed district heating networks, transporting hot water over long distances (over 10 km) with modest temperature losses (about 1 °C/km). Numerous LWR plants have been used successfully to provide domestic heating in addition to electricity.

Some concepts developed in the past were designed exclusively for the purpose of district heating. One of the main concerns with such reactors is the proximity to population centers. This can be addressed by low-temperature, low-pressure operating conditions, as well as passive safety features. In fact, the inherently safe SECURE concept mentioned earlier in this article was originally developed for district heating and with these safety concerns in mind (Leppänen, 2019). The most active R&D on dedicated district heating reactors is currently ongoing in China. Government companies, CNNC and CGN, are pursuing alternative designs in cooperation with Tsinghua university. CNNC is developing a 400 MW deep pool-type reactor (Jiafu et al., 1998), known as Yanlong, which does not require a pressure vessel and operates at low temperatures of less than 100 °C. CGN is pursuing a pressure vessel-type design, NHR200-II (Wenxiang and Dazhong, 1995), which has already obtained design certification from the Chinese regulatory authority, with plans in place for the construction of the first units.

LWRs have also been used for marine propulsion, although mostly for military applications. Commercial shipping currently accounts for a non-negligible fraction of global carbon emissions, therefore, it is an attractive market for advanced LWRs. The

requirements of compactness (small physical size) and long periods of operation without refueling lead to the choice of highly enriched uranium fuel in most military marine propulsion applications. For merchant ships, the enrichment will have to be lower than 20% to stay within the non-proliferation limit. A number of high-level conceptual design studies have been conducted recently, demonstrating basic design trade-offs. There are no firm follow-up plans for further development and commercialization of the technologies. Marine reactors fall into the SMR category and will be discussed in further detail in [Reitsma \(2021\)](#).

Proliferation-resistant LWR fuel

With regards to the fuel cycle front-end, LWRs can be considered more proliferation-resistant than many of the Gen-IV reactor concepts simply because they use lower enriched fuel. As for the back-end, most existing LWRs operate with an open fuel cycle, meaning that Pu and other fissile actinides remain in spent fuel which, following a period of cooling in reactor ponds and interim storage, is intended to be disposed in geological repositories. It has been argued that any isotopic composition of Pu originating from LWR spent fuel is potentially suitable for weapons use ([Mark et al., 2009](#)). It does, however, become more technologically challenging to use it if it has a less favorable isotopic vector and less of it is produced per unit energy generated. A number of strategies can be employed to reduce the quantity and attractiveness of Pu in spent LWR fuel.

Pu recycling would improve uranium resource utilization, but it can also be viewed as a strategy to mitigate the proliferation potential of spent LWR fuel. This is provided that the risks of Pu diversion during reprocessing and re-fabrication are deemed lower than those of direct disposal. Fuel recycling strategies are discussed in more detail in [Schwageraus \(2021\)](#).

The simplest approach to reduce the attractiveness of Pu in LWRs is to increase fuel burnup. As already mentioned, the burnup limits are primarily determined by Zr cladding performance (corrosion and hydrogen pick-up). However, with the development of new cladding materials discussed earlier, fuel burnup can be extended substantially. This will most definitely require higher initial fuel enrichment, which is currently limited to 5%. The fuel manufacturing and handling infrastructure can, in principle, be re-licensed, but at an additional cost, which can be prohibitive.

The total amount of Pu in LWR fuel grows monotonically with burnup, but this growth is not linear ([Fig. 6](#)). It is higher in the beginning and slows significantly towards the end. This is because the ^{239}Pu isotope concentration saturates with time as a result of its relatively constant generation rate being gradually matched by its destruction rate as fissions shift from ^{235}U to ^{239}Pu . Such non-linear behavior implies that, with higher burnup, less Pu will be generated per unit of energy produced by the fuel. Furthermore, all Pu isotopes that make it less attractive increase in quantity. The fraction of ^{238}Pu isotope, for example, which is mostly responsible for decay heat, more than doubles from about 3% at 50 MWd/kg to more than 7% at 100 MWd/kg ([Xu et al., 2005](#)). High decay heat generation of Pu with a high fraction of Pu^{238} is often cited as a particularly effective deterrent against proliferation. Studies have shown that isotopic mixes with ^{238}Pu comprising more than about 6% would be impractical to use in weapons, even for technologically advanced agents ([Kessler, 2007](#)). Even-numbered isotopes (^{240}Pu and ^{242}Pu) with high spontaneous fission source also increase with burnup, which would reduce the reliability of a weapon (reduce the probability of delivering a desired energy yield).

The concentration of ^{238}Pu in irradiated fuel can be increased by a variety of means. Many actinides would include ^{238}Pu in their transmutation chains under typical LWR conditions. Increasing the initial loading of these nuclides would result in larger quantity of ^{238}Pu after irradiation. Americium-241 is a product of relatively rapid β -decay of Pu^{241} and would inevitably be present in reactor-grade Pu. If separated ^{241}Am is available from countries practicing fuel reprocessing or as a by-product of warheads maintenance in nuclear weapons states, it can be added in small quantities to commercial LWR fuel and increase the end of life ^{238}Pu fraction ([Ronen et al., 2010](#)). Less than 0.2% of ^{241}Am would be sufficient to ensure over 6% of ^{238}Pu in the fuel end of life Pu isotopic vector. ^{241}Am has an additional advantage of having a high neutron capture rate initially, but, with irradiation, it depletes

Fig. 6 Evolution of Pu isotopes with burnup in a typical PWR fuel.

while generating highly fissile ^{242m}Am , increasing the fuel reactivity towards the end of life. It essentially serves as a fertile burnable poison, helping to reduce the fuel reactivity swing and reactivity control requirements.

Other additives to fresh LWR fuel can perform a similar function. It was shown that recycled and re-enriched uranium—with or without an addition of either recycled reactor grade Pu, Pu + MA or thorium—in a slightly modified fuel lattice would result in discharge fuel Pu vector with Pu 238 comprising more than 6% (Kessler, 2017). Doping LWR fuel with the mentioned additives, however, has never been considered commercially and these studies remain, at the moment, in the realm of academic research.

Replacing some or all of the fertile ^{238}U in fresh LWR fuel with thorium can drastically reduce the total quantity of Pu generated in their operation because thorium is located lower than uranium in the Periodic Table. A typical modern LWR would generate between 200 and 250 kg of Pu per GW $_e$ -Year of energy it produces. In practice, however, ^{238}U cannot be eliminated entirely from the fresh fuel because natural thorium (Th 232) is not fissile. Therefore, ^{232}Th has to be primed with a fissile component. The two most practical choices are enriched uranium or recycled Pu from other reactors or dismantled weapons. In the former case, the enrichment cannot be higher than 20% for the uranium itself not to become a proliferation concern. This implies that the remainder of uranium will have to be ^{238}U . In the latter case, fissile ^{233}U will be generated from ^{232}Th , which is also a weapons usable material with an even smaller critical mass than ^{235}U . In order to avoid the proliferation risk of ^{233}U diversion, the fresh fuel must contain some ^{238}U , so that, at the end of life, the content of ^{233}U in the uranium isotopic mixture will be less than 12% (which is equivalent to 20% enrichment limit for ^{235}U – ^{238}U mixtures, (Forsberg et al., 1998)). In both cases, the presence of ^{238}U is required, leading to the generation of Pu in spent fuel.

Another complication of using thorium in LWR fuel for improving its proliferation resistance is economic. ^{233}U tends to be generated from Th in LWRs much slower than Pu from U 238 . Therefore, in order to extract comparable amounts of energy from ^{233}U fissions in Th-containing fuel as from Pu in conventional enriched uranium fuel, one needs to keep the fertile Th part in the core for as long as possible. The initial reactivity of Th-containing fuels is typically lower because of the higher thermal absorption cross-section of ^{232}Th compared to ^{238}U . This initial investment of neutrons can be “repaid” by later fissions in ^{233}U , but only if a sufficient amount of ^{233}U is generated by allowing longer Th irradiation.

As mentioned earlier in this article, a homogeneous mixture of Th and enriched uranium does not lead to uranium savings (Galperin et al., 2002). The Pu production rate for such fuel, however, will be approximately halved, and the proliferation attractiveness of the Pu isotopic vector in spent fuel will also be slightly reduced. Physical separation of the fertile Th blanket and fissile uranium seed parts of the fuel on the micro-scale of fuel pellets in axial and/or radial direction increases the contribution of ^{233}U fissions to the total energy generated, increasing the fuel burnup (Schwageraus et al., 2004). As a result, the Pu generation rate reduces further, reaching about one third that of conventional uranium LWR fuel.

Macro-scale separation of fissile seed and fertile blanket parts of fuel assemblies can be realized in the form of a Seed-Blanket Unit (SBU), proposed by Radkowsky as an extension of the Shippingport LWBR idea. An additional advantage of the approach is that it allows refueling the seed and blanket parts with different frequencies. This is to allow the thorium blanket to remain in the core longer, further increasing the energy return per unit mass of initial fissile material invested (Radkowsky and Galperin, 1998). The macro-heterogenous configuration can be also realized on a scale of full conventional 17×17 pin fuel assemblies, as shown in Fig. 7 (Todosow et al., 2005). Such seed-blanket arrangements can reduce the Pu production rate to as little as one quarter that of conventional LWR fuel.

As mentioned in the discussion of high-conversion seed-blanket concepts, the main technological challenge of such configurations is to manage a much larger power imbalance between the seed and blanket regions than in typical LWRs, especially at the beginning of fuel life, when fission power in the blankets is small. Addition of fissile material to the blankets drastically reduces

Fig. 7 Schematic view of seed-blanket unit and whole-assembly seed blanket (WASB) configurations.

the effectiveness of spatial separation physics and leads to significant deterioration of both high fuel utilization and proliferation resistance performance characteristics.

Nuclear waste management

The issue of high-level waste management has many economic, political, environmental and other aspects, the nature of which is discussed in more detail in Metlay (2021) and Kadak (2021). Here, we simply address how LWR technology can be modified to improve some of the waste management characteristics of the fuel cycle. In a once-through fuel cycle, spent fuel assemblies are first cooled in water ponds at reactor sites for a number of years. Then, they are either moved to a temporary dry-cask storage or directly to geological repositories—if and when they become available. The costs of these storage activities strongly correlate with volume, decay heat load, radioactivity and radiotoxicity of spent fuel. Therefore, there is a clear incentive to reduce all of them. Decay heat affects the density of waste packages for transportation and storage, radioactivity affects the shielding, while radiotoxicity is relevant to the dose rates received by the public in case the content of waste packages leaks at any stage of handling or storage. The radioactivity, decay heat, and radiotoxicity are obviously closely correlated, but not exactly proportional to each other as different isotopes have a different energy release per decay and different radiotoxicity dose conversion coefficients.

The simplest option to reduce these characteristics is to increase fuel burnup. Fewer fuel assemblies would need to be discharged per year of reactor operation. The mass of fission products, however, is directly proportional to the energy produced (burnup). Therefore, each fuel assembly would be hotter, having implications for the costs of storage, transportation and handling.

Similar to the build-up of Pu isotopes, some fission products saturate with irradiation faster than others, leading to their non-linear accumulation. As a result, less decay heat is generated per unit energy produced by the fuel, at least initially, as shown in Fig. 8 (Xu et al., 2005). This is the period relevant to spent fuel pond storage. Although high-burnup assemblies would generate more heat, there will be fewer of them, potentially allowing an increase in pond storage capacity. Even though the total amount of FPs per unit energy produced is smaller, the isotopic mix of FP nuclides is different for high- and low-burnup fuel. This leads to a flip in the trend a few years following discharge and, shortly after, the high-burnup fuel at 100 MWd/kg would have up to 25% higher decay heat than 33 MWd/kg fuel (Fig. 8). After the decay of FPs, the decay heat is dominated by Pu and MAs, with the decay heat behavior favoring the high burnup between a few hundred to 10^5 years—the period of relevance for geological repository design.

As mentioned in the earlier discussion on non-proliferation, similar considerations apply to what extent LWRs' fuel burnup can be increased. Advanced fuel and cladding materials can certainly enable a transition to higher burnups, provided that higher than 5% enriched fuel becomes commercially available.

Thorium-based fuels in a once-through fuel cycle are often viewed as a more favorable option with respect to high-level waste management. This is based on the observation that, in conventional uranium-based fuel, the radiotoxicity and decay heat in the long term is dominated by the decay of Pu and MAs. In thorium-based fuel, many more successive neutron captures would be required to produce Pu and MAs. Therefore, the long-term characteristics of spent fuel can be improved. This, unfortunately, turns out not to be the case for a number of reasons.

Fig. 8 Decay heat power of high-burnup PWR fuel per GWe-Year relative to low-burnup fuel. Xu Z, Kazimi MS, and Driscoll MJ (2005) Impact of high burnup on PWR spent fuel characteristics. *Nuclear Science and Engineering* 151 (3): 261–273.

As mentioned earlier, thorium fuel will inevitably contain some uranium to mitigate the power imbalance in heterogeneous designs and dilute the generated ^{233}U down to the non-proliferation limit. At least 80% of that uranium has to be ^{238}U (due to the 20% limit on enrichment), which will generate considerable amounts of Pu and MAs.

Just like in uranium fuel, the short-term decay heat in thorium-based fuels is dominated by fission products rather than actinides. Although the isotopic mix of FPs is slightly different, the overall behavior is very similar for the two fuels, exhibiting similar trends as noted above in the high-burnup fuels discussion.

Although the quantities of Pu and MA in the thorium transmutation chain are practically negligible, it does contain long lived ^{233}U and ^{231}Pa , which would contribute substantially to radiotoxicity in the long-term.

Overall, thorium-based fuels in homogeneous, or micro- or macro-heterogeneous geometries introduced earlier, would have a relatively modest effect on the short- or long-term spent fuel characteristics, and are unlikely to simplify or reduce the costs of spent fuel storage and disposal substantially. In the most promising macro-heterogeneous seed-blanket arrangements, the number of discharged fuel assemblies per $\text{GW}_e\text{-Year}$ can be reduced by up to a factor of two compared to typical LWR fuel. The decay heat per unit energy is also lower by up to 40% for the first 5 years after discharge, becoming essentially identical to that of UO_2 for the next 100 years—the period most relevant to interim storage and geological repository construction costs. Thorium fuel decay heat becomes notably lower than UO_2 again in the period from 100 to 20,000 years with the largest difference of up to a factor of two at about 2000 years. In this period, however, the decay heat is less relevant and the dose rate (or radiotoxicity) of waste becomes a concern. Beyond 20,000 years, thorium fuel has up to an order of magnitude higher radiotoxicity, peaking at about 10^5 years exclusively due to thorium transmutation chain nuclides. (Tudosow et al., 2005).

The once-through fuel cycle options discussed above can offer only marginal gains with regards to simplification and cost reduction of high-level waste management. In order to realize a substantial benefit, long-lived actinides and fission products would need to be kept within a closed fuel cycle, that is, away from a geological repository. A major fuel cycle study in the United States, for example, has concluded that removing 99.9% of Am and Pu from spent fuel would increase the design capacity of Yucca Mountain repository by a factor of 5.4, while removing, in addition, Cs and Sr fission products—which dominate the short-term decay heat—could increase repository capacity by a factor of 43 (Wigeland et al., 2006) as compared to the direct disposal of LWR fuel without reprocessing.

In order to realize these gains, two attributes are necessary. First, an available fuel reprocessing infrastructure capable of keeping the TRU nuclides within the fuel cycle with minimal losses, high separation efficiency, and tolerance to high radiation and decay heat load of TRU isotopic mixes after multiple recycle passes. Secondly, one would need a reactor system capable of indefinite recycling of TRU nuclides with transmutation efficiency sufficient to constrain their growth. It has been established through multiple national and international studies that Gen-IV fast spectrum reactors are the preferred choice for this mission. LWRs, although less efficient than fast reactors in handling TRUs, are still capable of actinide transmutation and recycling. One such example is the RBWR, already mentioned in the context of LWRs with a high conversion ratio. In fact, LWRs operating in a closed fuel cycle can simultaneously accomplish multiple Gen-IV objectives, i.e., sustainability of resources, non-proliferation and long-term waste management, all using existing and well-proven reactor technology. Various aspects of fuel recycling in LWRs are addressed in further detail in Schwageraus (2021).

Chapter summary

LWRs are a well-understood and mature technology, ready for a large-scale worldwide deployment. Substantial improvements have been made to their design, manufacturing, and operating practices, with remarkable gains in efficiency, reliability, and safety. Modern Gen-III+ LWRs have pushed the boundaries on all fronts of the design and operational performance. Design simplifications and the adoption of passive safety systems have reduced the probability of core damage and large radioactive releases by more than two orders of magnitude over the past few decades. In light of these observations, it has been speculated that LWRs have practically reached their theoretical limits. Therefore, fundamentally different, new Gen-IV technologies are needed to make substantial, rather than incremental further progress in tackling the societal issues faced by the nuclear industry.

This article summarized and discussed some of the recent and ongoing research into advanced LWR designs with potentially high impact, showing that LWRs still have much to offer in each of the areas identified by the Gen-IV International Forum as objectives for the development of new systems.

It has been shown that LWRs can significantly increase the temperatures of heat delivery to their power conversion system, improving their thermodynamic efficiency. Their core power density can be increased, leading to capital cost reduction. Fuel burnup can be extended through employment of advanced fuel and cladding materials, as well as new geometrical arrangements, offering significant gains in safety, fuel utilization, proliferation resistance, and waste minimization. LWRs with a high conversion ratio operating on U–Pu or U^{233} –Th fuel cycles can achieve orders of magnitude higher fuel utilization than the current practice if fuel reprocessing infrastructure is available. LWRs capable of indefinite recycling of all trans-uranic nuclides would meet not only the resource utilization objective but, by keeping the Pu and MA within the fuel cycle, would also address the non-proliferation and long-term waste radiotoxicity concerns associated with direct disposal of spent fuel. Accident Tolerant Fuels in combination with passively safe designs can potentially offer significant capital cost savings through elimination of some of the safety systems and a simpler safety case, shortening the time necessary for licensing and construction. Finally, LWRs can be used to generate a variety of products other than electricity, such as district heating, hydrogen, and desalinated water, opening a wide range of commercial opportunities and increasing the contribution of nuclear energy to decarbonization of the world economy.

Even if Gen-IV reactors become technologically mature and commercially competitive in the near future, transition from an LWR fleet to new technologies would take many decades because LWRs currently being constructed are likely to have an 80-year life or even longer. Since LWRs are bound to be part of our energy system for a while, it is sensible to continue exploring and exploiting the advantages of this technology, which show promise in achieving many of the Gen-IV goals without the need to wait for Gen-IV reactors' availability and wide deployment.

Glossary

ATWS Anticipated transient without scram, a theoretical event where a major malfunction occurs and the shutdown system does not intervene.

Excess reactivity Maximum reactivity that a reactor can achieve.

Reactivity feedback Change in reactor multiplication factor upon change of an operational parameter.

TRISO Tri-structural isotropic particles of less than 1 μm in diameter, consisting of a spherical fuel kernel surrounded by multiple carbon/SiC layers with the purpose to retain fission.

Tritium Hydrogen isotope whose nucleus contains one proton and two neutrons.

Introduction

The fluoride-salt-cooled high-temperature reactor (FHR) uses solid fuel and molten salt coolant. Originally known as Advanced High Temperature Reactor or AHTR, the FHR concept was first proposed in 2003 (Forsberg et al., 2003) as the result of combining two technologies: TRISO coated particle fuel dispersed in a graphite matrix, developed for high-temperature gas-cooled reactors (HTGRs) starting in 1960s (Price, 2012; Goodjohn, 1991), and molten fluoride salt technologies developed within the molten salt reactor program conducted at the Oak Ridge National Laboratory (ORNL) in 1960s and 1970s (Haubenreich and Engel, 1970). Fluoride salt coolants provide a unique combination of properties: high volumetric heat capacity, low chemical reactivity with air and water, very low volatility at high temperature, effective natural circulation heat transfer, and high retention of many fission products (Andreades et al., 2014). When combined with coated fuel particles, they create a reactor design with outstanding safety features, high efficiency and potential economic advantages.

The following sections illustrate the main characteristics of FHR reactors, review some of the proposed design concepts, and summarize challenges and related R&D efforts.

Distinguishing features of FHRs

FHRs can be generally classified as graphite-moderated, molten-salt-cooled reactors. Nevertheless, the contribution of the salt to neutron moderation cannot be neglected. Rather, it is one of the features used to identify suitable salt options. In fact, although multiple fluoride salt mixtures can in theory be considered as coolants, $2\text{LiF}\text{-BeF}_2$, commonly referred to as flibe, is the almost universal choice due to its low neutron absorption, as long as lithium is enriched to 99.995% in ^7Li , and its large scattering cross section (Williams et al., 2006). As for any coolant, the reactivity feedback due to a change of its density is the result of opposite effects: a positive effect caused by reduced neutron absorption in the coolant and a negative effect caused by reduced moderation. The latter must be dominant in order for the total feedback to be negative, therefore, salts made of elements more absorbing and less moderating are not viable choices (Fratoni and Greenspan, 2011). Mixtures of fluorides are preferred to single-component salts for their considerably lower melting temperatures. Chloride salts, instead, are not suitable for thermal reactors due to chlorine relatively large absorption cross section. Molten salts are characterized by excellent heat transfer properties, high volumetric heat capacity, and high boiling temperature that enable near atmospheric pressure operation and ample margin to boiling in accident scenarios. The other defining characteristic of these salts is the high melting point that constraints the core's coolant inlet temperature above 500°C and requires adequate heating throughout the primary coolant system to prevent the salt from freezing. At the other end, the outlet temperature is constrained by the limits of the metallic structure in the heat exchangers and is typically set at around

700 °C. Even with such limitations, FHRs can provide heat at an average temperature higher than most other coolants and are suitable for industrial applications beyond electricity generation (Table 1).

Due to the use of TRISO particles, fuel density in the core is limited and requires enrichment typically between 10% and 20%. Although the use of thorium for breeding purposes has been considered, limited studies exist on such fuel option. FHRs are envisioned to operate at a power density of about 20 MW.m³ that is 2–5 times that of gas-cooled reactors, but lower than light water reactors and liquid metal cooled reactors (Table 1). When comparing electric power generated per unit volume of vessel, instead, FHRs value is about three times larger than the sodium-cooled reactor and less than one-third that of the PWR.

FHRs have unique safety characteristics. As the coolant outlet temperature—thus, the fuel temperature—is considerably lower than in gas-cooled reactors, extraordinarily large thermal margins are available between peak accident fuel temperatures and fuel damage temperatures. TRISO particles are an extremely robust form of fuel (Gerczak, 2021), but even in case of failure, the coolant presents high solubility for key fission products, particularly cesium, and could be credited as an additional barrier to the release of radionuclides. Operation at near atmospheric pressure combined with the salt high boiling point eliminates the possibility for accident events with abrupt coolant boiling and rapid control rod ejection as it can occur when there is a large pressure difference between inside and outside the reactor vessel as in light water reactors. Although design basis and beyond design basis events remain to be thoroughly addressed, the characteristics illustrated above combined with long neutron generation time, indicate that transient events in FHRs are expected to be slow and manageable. Finally, decay heat removal under emergency conditions can rely on the natural circulation of salt as long as adequate design solutions are implemented to prevent salt freezing.

Reactor designs

Three main designs have emerged for FHRs based on fuel geometry: a plate fuel design, a pebble bed design, and a stringer fuel design. Early designs also considered prismatic block fuel as gas turbine modular helium reactors (Potter and Shenoy, 1996; Fütterer, 2021), nevertheless, such option was quickly discarded because the average density of the fuel blocks would be lower than the salt density raveling some reactor operations like refueling (attempts to make the fuel blocks heavier adding ballasts were unsuccessful due to the excessive neutron absorption by the added material) (Casino Jr, 2006). This section summarizes.

Pebble bed designs

The Mark-1 Pebble Bed FHR (Mk1 PB-FHR), developed at the University of California, Berkeley (USA) (Andreades et al., 2016), is a 100 MWe design that features an annular pebble core cooled by flibe. The pebbles are 3 cm in diameter and use an annular fuel layer (Fig. 1). The center of the pebbles is made of porous carbon whose density varies in order to control the average pebble density. Due to their smaller size as compared to the conventional 6-cm diameter pebbles used in gas-cooled reactors (Reitsma, 2021), Mk1 pebbles have double the surface area per unit volume and half the heat diffusion length, enabling a substantial increase in power density while maintaining relatively low peak fuel particle temperature. Low fuel temperature reduces the thermal transient caused by hypothetical anticipated transient without scram (ATWS) accidents. Pebbles are slightly lighter than flibe, therefore, buoyant in the salt. They are inserted at the bottom of the core and slowly move upward driven by the salt drag and buoyancy. At the top of the core, defueling machines collect pebbles that are then reinserted into the core or discarded according to the measured burnup level. The Mk1 PB-FHR is expected to operate in continuous refueling mode with limited excess reactivity.

The internal vessel layout is illustrated in Fig. 2. Fuel pebbles form an annular bed in between two graphite reflectors. The external reflector is designed to withstand the lifetime of the plant, therefore, it is protected from radiation damage using a thin layer of graphite pebbles that are also continuously recirculated and can be replaced as needed. The central reflector is designed,

Table 1 Comparison of design parameters of a FHR with those of a 4-loop Westinghouse PWR, a gas-cooled reactor and a sodium-cooled fast reactor.

Reactor	Mk1 PB-FHR	PWR	PBMR	S-PRISM
Coolant	Flibe	Water	Helium	Sodium
Thermal power (MW)	236	3411	400	1000
Thermal efficiency (%)	42.5	32.0	43.8	38.0
Core inlet temperature (°C)	600	292	500	355
Core average outlet temperature (°C)	700	326	900	510
Core power density, (MWt/m ³)	22.7	105.2	4.8	321.1
Fuel enrichment (%)	19.9	4.5	9.6	8.9
Discharge burnup (GWd/tHM)	180	48	92	106
Reactor vessel diameter (m)	3.5	6.0	6.2	9.2
Reactor vessel height (m)	12.0	13.6	24.0	19.6
Vessel power density (MWe/m ³)	0.866	2.839	0.242	0.292

instead, as a modular unit for periodic replacement (roughly, every 10 years). The unique shape of its components (see Fig. 3) fulfills multiple functions: reduces stresses due to graphite shrinkage under irradiation, accommodates eight channel for insertion of buoyant control rods, houses 16 instrumentation guide tubes, and provides flow channels for radial coolant injection. The core barrel and other core internal structures are made of metallic material (316 stainless steel or in alternative 304 stainless steel or Alloy N) to enable near-term deployment.

Fig. 3 Mk1 PB-FHR center graphite reactor. Andreades C, et al. (2014) *Technical Description of the “Mark 1” Pebble-Bed Fluoride-Salt-Cooled High-Temperature Reactor (PB-FHR) Power Plant*. Technical Report UCBTH-14-002. Berkeley: University of California.

The Mk1 PB-FHR does not use an intermediate coolant loop and instead directly heats the power conversion fluid. It uses a refractory reactor cavity liner system in place of the conventional reactor guard vessel used in sodium fast reactors. All components for the Mk1 are modular and rail-transportable.

The Mk1 is designed to have negative fuel, moderator, and coolant temperature reactivity feedbacks. The reactivity control system uses buoyant rods both for normal reactivity control and shutdown. This is a passive shutdown mechanism as the buoyant rods insert if the reactor coolant temperature in the control-rod channel exceeds 615 °C, i.e., the buoyant stability limit. A separate shutdown system uses control blades inserted directly into the bed.

Emergency heat removal is achieved by employing a passive check valve that activates natural-circulation-driven heat transport to a set of three Direct Reactor Auxiliary Cooling System (DRACS) loops and ultimately to Thermosiphon-cooled Heat Exchangers (TCHXs) upon loss of flow condition.

A preliminary analysis of two ATWS (reactivity initiated accident and over-cooling transient) reveals that ample margins are available to accommodate the peak temperature experienced by the fuel during the event without compromising the integrity of the coated particles. Potential challenges could rather arise from the temperature limit of the metallic structures used to manufacture heat exchangers (Wang, 2018).

The Mk1 PB-FHR employs a nuclear air-Brayton combined cycle (NACC) that produces 100 MWe of base-load electricity when relying only on nuclear heat and increases this power output to 242 MWe using gas co-firing for peak electricity generation. Such co-firing capability brings a value proposition as additional revenues can be collected by providing dispatchable peak power at higher efficiency (66.4%) than natural gas plants (60%) in addition to the traditional base-load electrical power generation.

The Thorium Molten Salt Reactor Solid Fuel (TMSR-SF) is another pebble bed FHR design developed in China by The Shanghai Institute of Applied Physics (SINAP) (Dai, 2017). The TMSR-SF features a cylindrical core, 3-cm diameter pebbles, and (despite the name) 19.75% enriched uranium fuel. The core size is optimized for railway and highway transportation and the system is conceived as multipurpose, e.g., electricity production, hydrogen or methyl alcohol production, steam supply, heat delivering or seawater desalination. The total thermal power is 395 MWt (168 MWe). The system uses an intermediate salt loop and a combined air Brayton and steam Rankine cycle.

Commercial deployment of a PB-FHR is currently being pursued by Kairos Power LLC (KP; Kairos Power, n.d.). Its proprietary technology named KP-FHR features a cylindrical core and a steam conversion cycle.

Plate fuel designs

Plate or plank fuel consists of long and relatively thin planks made of carbon within which TRISO particles are dispersed. Early phase reactor concepts with plate fuel were developed at ORNL (Greene et al., 2011; Varma et al., 2012). They range from small 125-MWt plants for high temperature process heat production to large 3400 MWt reactors. The optimized plate design consists of two TRISO-bearing layers separated by a graphite layer to form a 2.55 cm thick plank. A hexagonal fuel element is obtained combining three sets of six planks as shown in Fig. 4. The assembly is completed by a central Y-shaped support structure and a channel box, both made of a carbon-carbon composite. The central structure also provides room for insertion of a control blade. The hexagonal assemblies (252 units) form a pseudo-cylindrical core with a 5.5 m long active region. When using a 9% enriched

Fig. 4 Transverse cross section of a group of fuel assemblies with plate fuel. Varma V, et al. (2012) *AHTR Mechanical, Structural, and Neutronic Preconceptual Design*. Technical Report ORNL/TM-2012/320. Oak Ridge National Laboratory.

uranium fuel, half of the core is replaced every 6 months that is at least twice the frequency of light water reactors; therefore, a rapid refueling scheme was designed based on visually guided automated refueling manipulators in order to limit the downtime to 3 days or less. The large size plant uses a super-critical steam cycle and an intermedium salt (KF-ZrF_4) loop. This FHR concept also features fully passive safety. The primary shutdown system consists of control blades to be inserted into the support structure at the center of the fuel assemblies. A secondary shutdown system is based on the injection of rare earth fluoride salt into the core inlet plenum triggered by the salt temperature exceeding a set limit. Natural circulation decay heat rejection is obtained by DRACS if other heat rejection systems are unavailable. Finally, the nuclear facilities including the spent fuel pool are located below grade, providing shielding from aircraft impact, and wind or waterborne missiles.

Stringer fuel designs

The term stringer fuel is here used to indicate fuel designs based on long cylindrical elements. Stringer fuel was originally used in the ORNL concepts before transitioning to plate fuel. Currently, stringer fuel is employed in FHR designs inspired by the British Advanced Gas-cooled Reactor (AGR) (Forsberg et al., 2019). The AGR-FHR, indeed, employs so-called fuel in radial moderator, or FIRM, assemblies that consist of a graphite cylinder with channels for coolant flow and holes to host fuel compacts (short cylinders made of a graphite matrix with TRISO particle fuel) as illustrated in Fig. 5.

The FIRM assembly is placed in a permanent graphite structure. As the length of graphite elements is typically limited to roughly 2 m, multiple short fuel sub-assemblies would be held together by a stringer for longer cores. The design of the FIRM fuel assembly is optimized to increase fuel burnup by reducing parasitic neutron losses. Fast neutrons are generated in the fuel, migrate to the graphite, are thermalized away from the fuel, and return back toward the fuel to cause fission, resembling the neutronic strategy used in CANDU, AGR, and RBMK reactors to increase fuel burnup by increasing neutrons' resonance escape probability.

This fuel assembly design reduces secondary graphite moderator waste generation because only the part of graphite that contains the fuel and sees significant fast neutron radiation damage is replaced. It also borrows high-temperature re-fueling procedures from the AGR and through a double tank system avoids salt freezing and high temperatures beyond design limits. Finally, the passive decay heat removal system employs heat pipes that remove decay heat upon reactor shutdown to avoid excessive temperatures but at lower temperatures coolant vapor formation inside the heat pipes is very limited, therefore, there is effectively no heat transfer and freezing of the salt is avoided.

R&D needs

The major challenges and R&D needs for the commercial deployment of FHRs are extensively discussed by Holcomb et al. (2013). A brief summary is provided in this Section.

Tritium production is largely recognized as the main challenge for FHRs. Tritium is produced upon neutron absorption in ^6Li that is continuously replenished from neutron absorption in ^9Be (Fratoni and Greenspan, 2011). Tritium is the only radionuclide that under normal operating conditions, with no fuel failure, can be potentially released to the environment as tritium penetrates structural alloys and the heat exchangers provide a pathway to its release.

Fig. 5 Notional design of the AGR-FHR FIRM assembly. Forsberg C, et al. (2019) Fluoride-salt-cooled high-temperature reactor (FHR) using british advanced gas-cooled reactor (AGR) refueling technology and decay heat removal systems that prevent salt freezing. *Nuclear Technology* 205(9): 1127–1142, 2019. <https://doi.org/10.1080/00295450.2019.1586372>.

It is estimated that at equilibrium the Mk1 PB-FHR, for example, produces 0.023 mol of tritium per effective full power day (EFPD), or 0.069 g/EFPD, or 670 Ci/EFPD (Andreades et al., 2014). This is 3500 times more tritium per MWe than the 700 Ci/year of a typical 1000-MWe PWR. Maintaining the total tritium emission rates similar to that for PWR would require recovering 99.9% tritium. Multiple tritium management strategies are being evaluated and capture in carbon beds outside of the reactor core appears particularly promising (Forsberg et al., 2017).

Fuel development and qualification is an additional R&D challenge. Although the United States is testing TRISO fuel as part of the gas-cooled reactor program, the different operating envelope in FHR core is likely to require additional testing. Furthermore, high throughput production of TRISO particles and high assay enriched uranium are not readily available and will require the development of dedicated infrastructure. Similarly, FHRs require lithium enriched at 99.995% in ^7Li . Several alternative techniques have potential for producing industrial scale volumes but a preferred process remain to be selected and deployed.

High temperature, neutron and gamma radiation and salt make a unique environment and a potential challenge for instrumentation. Although no fundamental hurdles have been identified, measurement performance requirements for instrumentation during normal and accident conditions need to be determined and demonstrated. Optical measurement and diagnostic technologies for liquid salt, gamma-based flow-meter for primary flow-loop measurements and electrochemical salt redox-condition measurement instrumentation are among the technologies under development for FHR applications.

Glossary

Breeding Ratio Ratio of the rate of conversion, by neutron capture, of fertile into fissile fuel to the rate of fissile fuel consumption.

Breed-and-Burn (B&B) Reactors Reactors that can breed fissile material and then fission (burn) a significant fraction of the bred fissile material without having to reprocess the fuel, when fed with make-up fuel the k_{∞} of which is smaller than 1.0.

Burnup A measure of the amount of fission energy released from a given quantity of fuel.

FIMA A unit of burnup defined as the fraction (usually given in %) of Initial Heavy Metal Atoms that has fissioned.

Neutron Flux Number of neutrons crossing a unit area per second.

Neutron Fluence Neutron flux integrated over time.

MOX Mixed Oxide Fuel, typically combinations of UO_2 and PuO_2 resulting from the reprocessing of used light water reactor fuel.

Infinite multiplication factor (k_{∞}) k_{∞} is the ratio of the rate of neutron production to the rate of neutron losses in a hypothetical infinitely large system without neutron losses to leakage.

Reactivity feedback A reactivity feedback implies that the ratio of the rate of neutron production to the rate of neutron losses (k_{eff}) changes due to a change in a performance characteristic such as temperature or density.

Smear density The fraction of the area inside a fuel rod cladding tube that separates the nuclear fuel from the coolant that is made up of fuel assumed to be at its nominal density.

Stationary Wave Reactors (SWRs) A subset of Breed-and-Burn reactors in which the fuel in the core is periodically relocated such that the breed-and-burn wave appears nearly stationary to an outside observer.

Traveling Wave Reactors (TWRs) A subset of Breed-and-Burn reactors in which a self-propagating breeding-and-burning wave travels through the static fuel material.

Traveling Wave Reactor (TWR[®]) Registered trademark of Traveling Wave Reactor under development by TerraPower, LLC.

Introduction and motivation

Present-day light water reactors (LWR) extract less than 1% of the potential energy of the uranium mined to make their fuel. About 90% of the unused uranium is in the form depleted uranium (DU, containing $\sim 0.25\%$ ^{235}U) left over from the enrichment process, and the remaining $>9\%$ is left over as used nuclear fuel (UNF). The world-wide stock of DU is about 1.6 million tons,¹ and every year more than 50,000 tons is added to this inventory (Lopez-Solis and Francois, 2017).

¹There is approximately 500,000 tons of DU stored in the form of UF_6 in the US alone (Schneider et al., 2007).

This material can, in principle, be utilized for energy production in nuclear reactors, primarily via conversion of ^{238}U by neutron capture to ^{239}Pu ² and subsequent fission. The conventionally proposed approach for attaining high uranium utilization is to use breeder reactors with fuel re-cycling. This process enables utilization (fission) of all the mined uranium minus inevitable losses in the reprocessing and fuel recycling operations. However, fuel reprocessing is a technically complicated, often costly and a politically difficult prospect in many countries. It has therefore been of great interest to explore fuel cycles that can attain high levels of uranium utilization without the need for reprocessing.

To enable a high utilization of uranium while using a once-through fuel cycle without reprocessing, a special class of nuclear reactors collectively known as “breed-and-burn” (B&B) reactors have been under consideration since the late 1950s (Feinberg and Kunegin, 1958). Any reactor containing fertile material (like ^{238}U or ^{232}Th) will inevitably breed and subsequently burn some fraction of the bred fissile material. *A breed-and-burn reactor, uniquely, relies solely on this process for criticality in its equilibrium state.* B&B systems may formally be defined as follows:

- A reactor whose operation includes the periodic or continuous loading and discharge of fuel may be defined as a B&B system if it is capable of sustaining an equilibrium state of critical operation fed only by fuel that, if the full core fuel inventory was made up of this feed fuel, would render the system subcritical³ (that is, the core infinite multiplication factor would be smaller than unity).
- A static fuel reactor (with no periodic or continuous loading and discharge of fuel) may be defined as B&B system if it is capable of initiating and self-propagating a breeding and burning wave through the fuel that, in its equilibrium critical state, is independent of the initial fissile starter fuel.

A large number of “battery” type fast reactor concepts have been developed that make very significant use of the breed and burn principle, typically with static (unshuffled) fuel maintaining criticality for extended periods of time and to significant levels of burnup (~ 10 – 15% FIMA). For some examples, see refs. (Greenspan, 2003; Wade, 2010; Grandy, 2011; ANL/CEA/JNC, 2005; Choi et al., 2011; Tsuboi et al., 2012; Brown, 1999). While these concepts may appear similar to B&B reactors (and sometimes are categorized as such Lopez-Solis and Francois, 2017), these systems do not fall in to the formal category of B&B reactors in this encyclopedia since they do not conform to the definitions as stated above. The breeding ratio of “battery” type cores is slightly above unity which is significantly smaller than the breeding ratio of B&B cores.

In order to establish initial criticality, the initial fuel loading of any B&B core has to contain an adequate amount of fissile material. While the definition of a B&B system formally allows for enriched or reprocessed feed-fuel even in the equilibrium state, the long-term aim of B&B reactor development is for fuel reloads to be made up of either depleted or natural uranium; a system like this will require no fuel enrichment and no fuel reprocessing. New B&B cores still require new fissile material for the first core loading to establish initial criticality. However, this material can be supplied by reconditioning⁴ of the fuel discharged from an existing B&B core (Petroski et al., 2011; Heidet and Greenspan, 2012a,b; Kim et al., 2017). The asymptotic requirement for uranium enrichment and reprocessing in a steady (not expanding) fleet of future B&B reactor systems is therefore zero.

Fast breeder reactors (FBRs) can also operate without fuel recycling using a once-through fuel cycle. Although the standard once-through FBR discharge burnup is two to three times higher than that of Light Water Reactors (LWRs), the uranium utilization of a once-through FBR is not significantly different from that of a once-through LWR because the level of uranium enrichment required to achieve criticality in the FBR is often three times that required to fuel the LWR. A conventional FBR operating without reprocessing is thus not able to use fuel resources more efficiently or make any use of the untapped energy potential of the available DU stockpiles.

In contrast, the uranium utilization of a B&B system will approach the fraction of the loaded uranium that has been fissioned. For realistic once-through solid-fuelled B&B systems with depleted or natural uranium reloads, this is around 20%, whereas for liquid-fuel designs or solid-fuel designs utilizing fuel reconditioning this value may be as high as 40%. B&B systems are therefore an extremely resource-efficient way of making use of the mined uranium without the use of fuel reprocessing technology.

If fully utilized for electricity production (in a system with 40% efficiency of converting thermal energy to electricity), each ton of mined uranium can in principle provide ~ 9 terawatt-hours (TWh) of electricity through fission. The electricity production possible from the currently available stockpiles of DU is therefore equivalent to current global electricity consumption for more than 500 years.⁵ Utilizing the B&B cycle without any reprocessing or fuel reconditioning, an amount of electricity corresponding to more than 100 years of current global consumption could in theory be unlocked just from this un-used depleted uranium waste

²There are existing reactor technologies that can operate using natural uranium as fuel, such as the heavy-water-moderated CANDU and the graphite-moderated Magnox type of reactors. Neither can run on a depleted uranium fuel loading. These reactors operate by fissioning fissile ^{235}U present in natural uranium, rather than by converting fertile ^{238}U , and thus achieve very low levels of uranium utilization in line with LWRs.

³A more ambitious definition would be that the equilibrium cycle of a B&B system should be fuelled only by fertile fuel with a ^{235}U content at or below that of natural uranium (0.711%). While this remains the longer-term objective of any B&B system, it does not formally define the reactor category. In a transitional phase while materials and fuels are being qualified for higher burnup and irradiation damage tolerance, prototype B&B systems will likely need to operate with equilibrium cycles fed by enriched fuel.

⁴Reconditioning typically means to simply reclad the fuel rods. This process inevitably involves the removal of gaseous fission products and refabrication of fuel rods, but reconditioning does not involve any kind of chemical fuel reprocessing operations.

⁵Current worldwide electricity consumption is $\sim 27,000$ TWh/year (BP., 2019), and the electricity potential from fully fissioning current DU stockpiles is 1.6×10^6 (tons) $\times 9$ TWh/ton = 14.4 million TWh. ($14.4 \times 10^6 / 27000 = 533$ years)

material without the need for additional uranium mining.⁶ The fuel supply implications of various nuclear fuel cycles are summarized in **Table 1**. By the time a significant fleet of B&B reactors will be deployed the inventory of DU waste will be significantly larger than the one accounted for in composing this table.

A brief history of breed & burn reactor development

The general principle of a breed-and-burn type of reactor was introduced by USSR scientists E. P. Kunegin and S. M. Feinberg in the late 1950s (Kunegin and Feinberg, 1958). The results of their initial research was briefly introduced to the world at the Second United Nations International Conference on the Peaceful Use of Atomic Energy in 1958 with the following comment (Feinberg and Kunegin, 1958):

I should like to draw attention to a possible modification of the conventional fast breeder reactor scheme, in which the reactor has only an active zone, i.e., there is no separate breeder zone and so there is no longer any need for chemical and metallurgical reprocessing of the fuel in the breeder cycle as a whole. A fast neutron reactor is continuously loaded with blocks of ^{238}U . The blocks are also continuously unloaded, after about 30% of the uranium has been consumed, when they contain about 7% of plutonium. Criticality is maintained because of the plutonium which accumulates in the reactor. Theoretical calculations for the breeder, which have been made by Mr. Kunegin, show that such a scheme is feasible. [...] An estimate has shown that the dimensions and the overall power of a profitable plant might have to be very large. Moreover, there are as yet no fuel elements capable of ensuring a burn-up of 30% of the uranium.

The issues identified by Feinberg & Kunegin in the late 1950s remain the main challenges to B&B reactor development to this day, namely a requirement for very low neutron leakage (large core dimensions) as well as fuel and structural materials that can survive very high levels of burnup and neutron irradiation damage.

In 2007, a small team at Intellectual Ventures funded by Bill Gates initiated work on physics and engineering concepts of B&B reactors and in 2008 TerraPower, LLC (TerraPower[®]) was officially launched (TerraPower, 2015). In the years following this announcement, a large number of groups have started research on the topic, making it difficult to give a full and exhaustive overview of all major B&B research developments after this point. An extensive, though certainly not complete, chronologic history of B&B research and development from the late 1950s up until 2007 is shown in **Fig. 1**. The first or most important publication from each identified B&B research group in **Fig. 1** is given in references: (Feinberg and Kunegin, 1958; Fuchs and Hessel, 1961; Kouts et al., 1979; Atefi, 1980; Slesarev et al., 1983; Feoktistov, 1988; Goldin and Anistratov, 1992; Seifritz, 1995; Teller et al., 1996; Toshinsky, 1997; Akhiezer et al., 1999; Sekimoto and Ryu, 2000; Van Dam, 1998; Van Dam, 2000; Khizhnyak, 2001; Pilipenko et al., 2003; Fomin et al., 2005; Chen et al., 2005; Yarsky, 2005; Driscoll et al., 2005; Heidet and Greenspan, 2010; Gaveau et al., 2005; Gilleland, 2008). Some of the more recently published research studies on the topic are presented in ref. (Pavlovich et al., 2007; Rusov, 2011; Hartanto and Kim, 2012; Osbourne et al., 2012; Choi et al., 2013; Si, 2013; Heidet and Greenspan, 2013a,b).

Types of breed & burn reactors

B&B reactors come in three basic flavors: Standing Wave Reactors (SWRs), Traveling Wave Reactors (TWRs), and molten-salt B&B (BBMSRs; Greenspan, 2012). They are presented below in the chronological order in which they were invented.

Table 1 Fuel utilization comparisons between LWRs and DU-fed B&Bs (Greenspan and Heidet, 2011; BP., 2019).

Concept	Uranium utilization	Uranium utilization relative to LWR	Years of current global electricity consumption from current DU stockpiles
Light Water Reactor (LWR)	~0.6%	1.0	N/A
Once-through FBR	Up to ~1%	1.5	N/A
LWR with recycling reprocessed mixed-oxide (MOX) fuel	~1%	1.5	N/A
Solid-fuel B&B reactor with DU fuel reloads, No fuel reconditioning	~20%	> 30	> 100
Solid-fuel B&B reactor with DU reloads and one fuel reconditioning or a fluid fuel B&B reactor	Up to 40%	> 65	> 200
Breeder reactor with fuel recycling	> 95%	> 150	> 500 ⁵

⁶However, in order to establish initial criticality, B&B cores will require enriched uranium (some additional uranium mining and enrichment) or another form of fissile material.

Fig. 1 The history of breed-and-burn reactor R&D until 2008.

Standing wave reactor (SWR)

A “standing wave reactor” (SWR), the type of B&B originally proposed by Feinberg and Kunegin, is essentially a type of fast breeder reactor with an exceptionally good neutron economy (very low neutron leakage, hard spectrum and high core actinide density) which enables it to operate on the unique B&B-type fuel cycle. In SWRs, fuel assemblies are periodically shuffled in the core, burned fuel batches are discharged and new fertile fuel assemblies are loaded. Fertile fuel batches, ideally containing depleted or natural uranium fuel, are typically loaded at the low-worth radial periphery of the core⁷ and are subsequently moved into inner regions of the core before being discharged when the target equilibrium cycle burnup is reached. The location of “breeding and burning” in an SWR therefore stays fairly stationary while the fuel “travels”, which is the feature which gives this type of B&B system its name (Standing, Stationary or Soliton Wave Reactor – SWR). Apart from the characteristics that typically define any nuclear reactor technology (the spectrum and type of fuel & coolant), SWRs can be broadly differentiated by the type of shuffling strategy employed. A large variety of optimized 2D B&B shuffling strategies have been developed (Toshinsky et al., 2000; Toshinsky et al., 1999; Heidet and Greenspan, 2013a,b; Qvist et al., 2015; Heidet and Greenspan, 2013a,b; Kuwagaki et al., 2018; Kuwagaki et al., 2019; Zheng, 2014; Su’ud et al., 2013), while more limited work has been done on three-dimensional shuffling for SWRs (Qvist and Greenspan, 2014a,b; Qvist et al., 2015). Some examples of SWR concepts,

⁷Thereby capturing excess fission neutrons generated in inner, high fission density regions of the core and minimizing neutron leakage out from the core.

distinguished by the overarching approach to fuel shuffling, are given in [Table 2](#). TerraPower, LLC's TWR concept is also a SWR but uses the TWR[®] trademark designation for reasons discussed in Chapter Traveling wave reactor (TWR).

Traveling wave reactor (TWRs)

TWRs, a category of B&Bs first explored by Lev Feoktistov in the late 1980s ([Feoktistov, 1988](#)),⁸ are cores traditionally defined to have static (unshuffled) fertile fuel with a small, enriched, “starter” region typically located at one axial end. The fissile starter region establishes criticality and initiates a self-propagating breeding-and-burning wave that travels through the static fuel material toward the other axial end. The stages of operation for this reactor class are shown in [Fig. 2](#), in which the third state refers to the established B&B equilibrium in which all the main parameters, such as flux, flux profile and power level of TWRs remain essentially constant as the breeding and burning “waves” self-propagate through the core.

In principle, the fissile starter zone of TWRs could be omitted by instead irradiating a portion of the fuel with an external neutron source or an internal accelerator driven spallation neutron source ([Cisneros et al., 2012](#)).⁹ The leading Japanese TWRs researcher Hiroshi Sekimoto has dubbed this type of principle “CANDLE”, as the burnup wave propagation is similar to a burning candle.¹⁰ While this wave propagation principle is very elegant and simple, it has so far proven very difficult to engineer a commercial design that makes full and direct use of it. To establish a self-propagating B&B wave through stationary fuel material with low fissile content, a very high level of burnup and associated peak fast neutron fluence is needed, which exposes core structures (like the fuel rod cladding and fuel assembly duct wall steel) to high levels of radiation damage ([Heidet, 2021](#)).

There are essentially five different possible options to configure TWRs, which are defined by where in the core that the initiating fissile fuel is placed, as shown in [Figs. 3 and 4](#). For axially propagating burnup waves, the fissile fuel portion can either be placed at one axial end

⁸Lev Petrovich Feoktistov (1928–2002) was a leading USSR scientist originally active in the development of thermonuclear weapons. In the 1970s he left this work behind to join the Kurchatov Institute and became a very active proponent of nuclear disarmament and a member of the Pugwash movement. In the USSR and present-day Russia, the “Traveling Wave” is also known as the “Feoktistov wave”, named after its discoverer.

⁹Studies have also examined fusion/fission hybrids where neutrons from the fusion reaction is the driving source for a breeding and burning fission blanket ([Brown et al., 2016](#))

¹⁰An alternative analog would be the burning of a matchstick, where the match head is the equivalent of the fissile starter region that initiates the burning wave, which then propagates axially and leaves behind burnt unproductive fuel-ash as it propagates down the match.

Breed & Burn Molten Salt Reactor (BBMSR)

In addition to solid-fuel options, the B&B fuel cycle has more recently been shown to be possible in a fast-spectrum fluid fuel molten salt type of reactors (BBMSR) with both single fuel-salt and multiple fuel-salt designs. In a BBMSR system, the initial fuel load contains a significant fraction of fissile material to establish criticality. The system then operates by continuously feeding in fertile fuel salt and simultaneously discharging homogeneously mixed molten fuel with an equilibrium-state average burnup level of up to 10–40% FIMA (Martin et al., 2017; Hombourger, 2018; Hombourger et al., 2019; Kramer, 2018; Krepel and Kramer, 2021). Some examples of BBMSR concepts under development are given in Table 4.

Fundamentals of breed-and-burn reactor physics

Neutron spectrum and fuel cycle

The B&B fuel cycle puts extremely challenging requirements on the neutron economy, particularly when aiming to realize its full potential in systems that in equilibrium are fed only by fertile fuel such as a natural or depleted uranium. All major B&B design efforts rely on a hard (fast) neutron spectrum to maximize ν (the average number of neutrons per fission) and to minimize neutron parasitic absorption. The fertile-feed B&B fuel cycle is not possible in any type of reactor system with a thermal or intermediate neutron flux spectrum. Thorium-based B&Bs have been shown to be possible at least in theory (Hombourger et al., 2019), but the Uranium-Plutonium fuel cycle is the main development path for all major current B&B efforts due to its superior neutron economy in a fast spectrum.

The neutron balance concept

The neutron balance concept is a simple mathematical framework for analyzing the requirements and limits of discharge fuel burnup in B&B systems. Unique among nuclear fuel cycles, the B&B reactor requires a certain minimum level of discharge burnup to be attained in its equilibrium cycle.¹² Rather than trying to increase this level (as is typically the goal for designers of nuclear energy systems), the main aim of the B&B system designer is to minimize the required discharge burnup level in order to minimize problems related to irradiation damage of structural materials.

To explore the physical principles of the B&B fuel cycle, we follow a batch of fertile fuel in a SWR B&B core from its introduction until its discharge. We follow the derivation used by Heidet and Greenspan et al. (Heidet et al., 2009; Heidet, 2010; Heidet and Greenspan, 2012a,b; Petroski et al., 2010; Petroski et al., 2011), which in principle is similar to the method used earlier by Yu et al (Yu et al., 2002). This generalized methodology is valid regardless of the type of B&B system studied.¹³ A fertile B&B fuel batch will pass five distinct operating milestones as relating to the neutron balance as defined below (and shown in Fig. 5).

1. Fuel introduction to core

A fuel batch of fertile fuel (ideally depleted or natural uranium) loaded to the core initially produces far fewer neutrons than it absorbs, and its infinite multiplication factor - k_{∞} , is thus significantly lower than unity. The fuel is consuming excess neutrons that leak from fissions occurring in other, higher k_{∞} , fuel regions. As burnup progresses, neutron capture converts fertile material into fissile isotopes thus increasing the fissile fuel concentration and, along with it, the batch k_{∞} .

2. Net neutron producer

¹²Equilibrium for an SWR means that the system parameters between subsequent burn cycles are identical, for the TWR and MSRBB it means the state when system criticality and the B&B wave propagation no longer relies on the initial fissile fuel load.

¹³For a TWR, the batch simply corresponds to a region of stationary fertile fuel. For an MSRBB the analog of a “batch” is simply a unit volume of fertile fuel salt, starting from its introduction in an equilibrium core.

Fig. 5 Example of a B&B neutron balance integral with balance points marked (unit cell, sodium-coolant, metallic U–6Zr fuel, HT9-steel structure; $L = 0$).

Once the batch k_{∞} reaches unity, it turns from a net neutron consumer to a net neutron producer. From this point on, the batch starts to pay back its debt to the neutron economy.

3. B&B neutron balance point #1

At this point, the burnup-integrated neutron production and loss (absorption + leakage) of the batch are equal, and the overall neutron economy is balanced. This point corresponds to the lowest level of *average discharge burnup* that an equilibrium cycle of the B&B core can be operated at. This is the main design point of interest to the B&B core designer.

4. Net neutron absorber

Due primarily to the accumulation of fission products, the excess neutron production diminishes after having reached point 3. At point 4, the neutron absorption rate equals the production rate (k_{∞} is again equal to one), and after this point the batch again becomes a net neutron absorber. In the neutron economy, the net neutron “profit” accumulated between points 3 and 4 is now being spent to “drive” the high-burnup subcritical fuel on to point 5.

5. B&B neutron balance point #2

Once the net neutron gain accumulated between point 3 and 4 has been consumed, the net neutron excess is again 0, and the neutron economy is balanced for the second time. This corresponds to the maximum level of average discharge burnup that an equilibrium cycle of a B&B system can, in theory, be operated to.

The values (in terms of burnup) that correspond to points 1–5 can be quantified using a very simple neutron balance analysis. The point of primary interest for the B&B reactor designer is point 3, the minimum burnup required for the system to operate in a B&B mode. The total number of neutrons produced (P) by N_{HM} atoms of actinide fuel up to a level of burnup Bu in units of FIMA is given by Eq. (1) in which $\bar{\nu}$ is the average number of neutrons per fission:

$$P = N_{HM} \int_0^{Bu} \bar{\nu}(Bu) dBu \quad (1)$$

Since the infinite multiplication factor is the neutron production¹⁴ divided by neutron absorption, the total number of neutrons absorbed in the fuel up to a burnup Bu is:

$$A = N_{HM} \int_0^{Bu} \frac{\bar{\nu}(Bu)}{k_{\infty}(Bu)} dBu \quad (2)$$

Combining Eqs. (1) and (2), the points in burnup (Bu) where the integrated neutron production and absorption are equal are given by the solutions to:

$$\int_0^{Bu} \left(\bar{\nu} - \frac{\bar{\nu}}{k_{\infty}} \right) dBu = 0 \quad (3)$$

¹⁴Which includes neutrons from fission as well as from (n,2n) and (n,3n) reactions (Yang et al., 2016).

Fig. 6 Example of the k_{∞} -evolution of a batch of metallic depleted uranium (U–6Zr) fuel in a unit cell with sodium-coolant and HT9-steel structure.

In a real system, neutrons are also lost to leakage and to burnup reactivity control systems. Combining the loss terms for neutrons into a single term denoted as L , Eq. (3) becomes the *neutron balance equation*:

$$\int_0^{Bu} \bar{v} \left[1 - \frac{1}{k_{\infty}(1-L)} \right] dBu = 0 \quad (4)$$

To illustrate the points of neutron balance of a typical B&B system described in the equations above, neutron transport calculations were performed in a 0-dimensional geometry representing a typical sodium-cooled fast reactor with metallic alloy of depleted uranium (0.25% ^{235}U) with 6 wt% Zirconium (U–6Zr) feed-fuel using the Serpent neutron transport code (Leppänen, 2010) with ENDF/B-VII.0 cross-sections (Chadwick, 2006). The resulting neutron balance plot (the left side of Eq. 4) is given in Fig. 5 and the k_{∞} evolution plot in Fig. 6.

For the B&B core designer, the extended neutron balance (ENB) method, an expansion of the basic neutron balance presented above, can be used to further enable parametric and sensitivity analyses of candidate B&B core design options (Qvist and Greenspan, 2016; Qvist, 2013). In practice, the value of neutron loss probability (L) needs to be kept well below 10% for the fertile-feed B&B cycle to be possible at all, and below $\sim 6\%$ in order to limit peak levels of fuel burnup and irradiation damage to realistic levels ($\sim 20\%$ FIMA). In a metal-fueled core, increasing the neutron loss from $L = 0\%$ to $L = 3\%$ corresponds to an increase in the average minimum required burnup of about 3% FIMA (from 13% to 16.5%), while a further increase to $L = 6\%$ raises the minimum burnup to just over 20% FIMA (Qvist and Greenspan, 2016).

Engineering aspects of B&B systems

Minimum burnup requirement & irradiation damage

The main engineering challenge of any system relying on the B&B principle is the minimum required discharge burnup and the associated fast neutron fluence and neutron irradiation damage to the fuel and structural components of the core. The ambition to minimize the peak fuel burnup and irradiation damage drives many of the main design and material choices of B&B systems.

Current fast reactor structural steels were so far exposed to a peak fast neutron fluence of $\sim 4 \times 10^{23} \text{ n/cm}^2$ ($E > 0.1 \text{ MeV}$), corresponding to a radiation damage of $\sim 200 \text{ DPA}$ (displacements per atom) (Toloczko et al., 1994). Solid-fuel B&B designs with a DU-feed-fuel suffer peak equilibrium cycle neutron irradiation damage to the cladding and fuel assembly duct steel structures starting from a theoretical low of around 350 DPA (for very large 3D-shuffled SWRs) to well over 1000 DPA (for TWRs). Structures in more near-term realistic designs utilizing conventional 2D-fuel shuffling B&Bs suffer a peak neutron irradiation damage in the range of 500–700 DPA. The difference in peak neutron damage between the 2D and 3D shuffling systems is due to the theoretical possibility of greatly reducing the axial peaking factor of burnup, fluence and DPA in the 3D-shuffled system. Molten salt reactor fuel is liquid and thus does not suffer lasting irradiation damage. BBSRs have no solid in-core structures in high-flux regions, and thus suffer much lower levels of peak structure DPA while operating on a B&B type fuel cycle. Representative burnup and irradiation damage levels of B&B systems are summarized in Table 5.

There are essentially five current approaches to tackle the challenge of high neutron irradiation damage levels in solid-fuel B&B systems:

Table 5 Approximate ave. burnup and irradiation damage in B&B systems fed by DU.

B&B Type	Required average minimum discharge burnup (% FIMA)	Approx. min. Peak structure DPA
TWRs (Tak et al., 2012; Sekimoto, 2007)	~30–40%	> 1000
2D-shuffled SWR (Qvist et al., 2015) and TerraPower TWR® (see Chapter Traveling wave reactor (TWR))	~15–20%	~500
3D-shuffled SWR (Qvist et al., 2015)	~17–25%	~350
BBMSR (Martin et al., 2017; Hombourger et al., 2019)	~10–40%	N/A due to no solid in-core structures. (the vessel can in theory be protected by sacrificial replaceable materials)

1. Increasing the irradiation damage tolerance limits for steels

Samples of HT9 steel previously irradiated to ~200 DPA in the FFTF reactor in the USA have now been further irradiated in the BOR-60 reactor in Russia to extend the knowledge base for HT9 steel to ~300 DPA (Maloy, 2015). TerraPower, LLC is developing optimized versions of HT9 steel with the eventual aim of tolerating damage well above 500 DPA without excessive swelling or material property degradation. In parallel, Oxide Dispersion Strengthened (ODS) alloys are under development and testing to further expand irradiation tolerance (Maloy, 2015). Ion irradiation results up to 500 DPA indicate that ODS steels such as MA957 and 14YWT, as well as TerraPower's optimized ferritic martensitic steels may outperform HT9.

2. Minimizing the peak irradiation damage by design

This involves, for SWRs, optimizing the fuel shuffling strategy to minimize peaking factors and in general to minimize the neutron leakage probability.

3. Use of enriched feed fuel at equilibrium state

While materials are being qualified for higher limits, it is highly likely that the first generation of B&B reactors will use enriched fuel rather than fertile fuel in order to enable a B&B equilibrium cycle at lower burnup and irradiation damage. This is the approach presently taken by TerraPower (Gilleland et al., 2016) as further described by Hejzlar (Hejzlar, 2021).

4. Use of source-driven subcritical B&B system

The idea is to reduce the minimum burnup and, hence, also irradiation damage at which the fuel need be discharged by supplementing the neutrons emitted in fissions in the B&B system by neutrons generated by an external neutron source. This will move Point 3 in Fig. 5 to the left; that is, will lower the minimum required burnup. The two potentially relevant external neutron sources are spallation reactions induced by high energy ions impinging on a heavy metal such as lead or tungsten, and fusion reactions to be generated in future fusion devices (Moses et al., 2009; Kramer et al., 2008; Abbott et al., 2008; Meier et al., 2014). Another approach that is described in detail by Greenspan in Chapter Seed driven breed-and-burn blanket reactor concepts is to use excess neutrons that are generated by a high k_{∞} critical fission region (the "seed") to drive a subcritical B&B blanket that radially surrounds the seed.

5. Periodic replacement of structural materials and reconditioning of fuel

One design solution investigated by Sekimoto and colleagues for TWRs is to re-clad the fuel rods with new steel every ~10 years of operation to limit peak damage levels (Nagata and Sekimoto, 2007; Nagata et al., 2009). At UC Berkeley, researchers have looked in to the possibility of B&B operation with periodic and limited fuel reconditioning (Heidet, 2010; Greenspan and Heidet, 2011; Greenspan, 1998), as well the option to double-clad the fuel (Di Sanzo et al., 2011).

To enable the required high levels of burnup in the fuel, solid-fuel B&Bs (typically employing metallic fuel) are designed with a low smear density (60–75%) which allows for sufficient fuel swelling without causing excessive stress in the cladding. To limit fission gas pressure in the cladding tubes, the fuel rods are typically designed to vent gaseous fission products to a fission-gas plenum above the active fuel zone. A number of fission gas vent-to-coolant devices have been developed for both sodium cooled fast reactors (SFR) and gas-cooled reactors (General Atomics, 1974; Schleicher et al., 2013; Farmer et al., 2006; Steward, 1978; O'Neill, 1965; McNelley, 1964; Martini and Gerosa, 1973; Dorner and Sommer, n.d.; Smidt and Sommer, 1965; Lipps, 1968). A couple of examples of fuel rod designs optimized for use in B&B systems, with annular metallic fuel and fission gas venting, are shown in Fig. 7.

Fuel and coolant choices

A large number of potential B&B fuel and coolant options have been assessed in scoping studies (for example Petroski et al., 2013; Qvist and Greenspan, 2016). An ideal B&B fuel candidate has to offer the following characteristics:

Fig. 7 Example of a vented B&B fuel rod design (not to scale) (Qvist et al., 2015).

Fig. 8 Unit-cell neutron balance analysis results for different fuel types (zero neutron loss, sodium coolant, HT9 steel structures), nitride-fuel is 99% ^{15}N (Qvist and Greenspan, 2016).

1. Maximized actinide atom density in the core
2. Minimized moderation of neutrons by nonactinide components of the fuel
3. Minimized absorption of neutrons by nonactinide components of the fuel

The effective core-averaged actinide density depends on the fuel volume fraction, fuel chemical composition, fuel nominal density and smear density. Metallic fuels (typically uranium alloyed with molybdenum or zirconium) have consistently been found to be the most viable fuel options for solid-fuel B&B reactors. It is not possible to sustain *fertile-feed* B&B operation using the oxide fuel type (UO_2) in use in light and heavy water reactors. Non-metallic fuel options such as U_3Si_2 and U^{15}N are potentially viable for B&Bs but require a higher burnup cycle than metallic alternatives. Carbide fuels may only work in very low-leakage systems at very high levels of discharge burnup and, hence, neutron irradiation damage. An example of the neutron balance integral (left side of Eq. 4) for various solid-fuel options in an example sodium-cooled system with HT9-steel structure is shown in Fig. 8. The corresponding technical data for the fuel options is summarized in Table 6.

Essentially all major fast reactor coolant options have been studied and shown to be viable for solid-fuelled B&B reactor applications (for examples see Tables 2 and 3), including:

- Sodium
- Lead & Lead-bismuth eutectic
- He and CO_2 gas

For fluid-fuelled BBMSR systems, only chloride-based fuel (and coolant) salts, with chlorine enriched in ^{37}Cl , have so far been shown to be neutronically viable. The fuel options studied and found viable with fertile feed-fuel include various compositions

Table 6 Fuel parameters for B&B core in Fig. 8 (Fuel/coolant/structure vol. fraction = 43.7%/39.9%/16.4% Qvist and Greenspan, 2016).

Fuel type	UO ₂	UN	UC	U-10Zr	U-10Mo
Fuel mass fraction of actinide (%)	88.1	94.4	95.2	90	90
Smear density (%)	85	85	85	75	75
Fuel porosity (as manufactured, %)	6	6	6	0	0
Fuel density at operating temp. (g/cm ³)	10.26	13.59	12.58	15.80	16.70
Fuel density after swelling (g/cm ³) ^a	8.73	11.56	10.81	11.86	12.54
Fuel actinide density (g/cm ³)	9.05	12.84	11.98	14.22	15.03
Swollen fuel actinide density (g/cm ³)	7.69	10.91	10.30	10.67	11.29
Core fuel density (g/cm ³)	4.48	5.94	5.49	6.90	7.30
Core actinide density (g/cm ³)	3.95	5.61	5.24	6.21	6.57
Core fuel non-actinide density (g/cm ³)	0.53	0.33	0.25	0.69	0.73

^a“Swelling” here refers to the state at full radial swelling (out to the inner wall of the cladding) and no axial swelling. The metallic fuels will suffer axial swelling (the value of which can vary greatly with different compositions) which has not been accounted for in this table.

Table 7 Passive reactivity control concepts developed specifically for B&B reactors.

Reactivity control system concept	Actuation signal	Absorber
TWR Thermostat (Teller et al., 1996)	Coolant temperature	⁶ Li
Autonomous Reactivity Control (ARC) (Qvist and Greenspan, 2014a,b; Qvist et al., 2016)	Coolant temperature	⁶ Li
FAST (Hartanto et al., 2015; Hartanto, 2015; Hartanto et al., 2016a,b)	Coolant temperature and coolant flow rate	B ₄ C
SAFE (Hartanto, 2015; Hartanto et al., 2016a,b)	Coolant temperature	B ₄ C

of NaCl-UCl₃, NaCl-UCl₃-UCl₄, UCl₄-UCl₃ as well as pure UCl₄ and a mixed Uranium-Thorium feed fuel composition of NaCl-ThCl₄-UCl₄ (Hombourger et al., 2015, 2017, 2019; Martin et al., 2017; Koivisto, 2019).

Designing for inherent safety

An important design objective of fast reactor cores is inherent safety – that is, the combined effect of all the inherent changes in the core due to loss of coolant or due to increase in power will result in the slowing down of the chain reaction without active intervention of reactor operators. It is very difficult to design a very low-leakage fast reactor core, such as required for B&B systems, to have a combination of inherent reactivity feedbacks to keep core component temperatures sufficiently low in accidents. If the neutron leakage probability at nominal operating conditions is small, which is a requirement for a good neutron economy, the negative feedback associated with loss of coolant will have a small negative impact on the core reactivity. Moreover, the negative reactivity feedbacks due to core radial expansion and due to fuel axial expansion caused by core temperature increase in physically large low-leakage core are smaller as compared to conventional smaller, higher-leakage cores (Wade and Fujita, 1989; Qvist and Greenspan, 2012). The challenge of designing large low-leakage fast B&B reactor cores to be inherently safe has led to the development of passively actuated engineered reactivity control systems, as summarized in Table 7. A very extensive review of other applicable solutions (although not specifically developed for B&B systems) is available in ref. Qvist (2017).

Summary

After many decades of mainly theoretical studies, the physics of B&B systems is now well understood and established, and the technology is now being commercialized. The B&B fuel cycle offers the potential of extremely efficient use of existing uranium resources with minimal need for mining, enrichment and reprocessing. The challenges identified in the very first publication on B&B systems in the late 1950s, the requirement of a large low-leakage core and high burnup, still present a challenge to present-day B&B developers. However, a wide range of possible solutions are being developed to overcome these issues. This chapter serves as an introduction to the general concept of B&B and the basic physical principles involved. In the following four chapters, researchers and commercial reactor vendors present in greater detail specific B&B reactor systems and their current state of development. Chapter Molten Chloride Fast Reactors (MCFRs) and Traveling wave reactor (TWR) presents the efforts of Terrapower in developing solid and liquid fuel B&B reactors respectively. In Chapter CANDLE Reactor Concept, Professor Hiroshi Sekimoto presents the concept of CANDLE, perhaps the most well-known and most comprehensively researched of all traveling-wave B&B systems to date. In Chapter Seed driven breed-and-burn blanket reactor concepts, Professor Ehud Greenspan presents the novel “seed-and-blanket” concept that makes extensive use of the B&B principle in a solid-fuelled system while adhering to existing irradiation damage limitations and constraints.

B&B development and commercialization will likely follow a stepwise approach, with initial prototype reactors either making partial use of the B&B principle or first operating on a low-enriched feed-fuel rather than the more challenging fertile fuel such as natural or depleted uranium. The key enabling technology for conventional solid-fuel B&B technology is the development of fuels and structural steels that can tolerate very high levels of burnup and irradiation damage. In the last few years, a completely new category of B&B systems is being developed that may offer an effective way to circumvent the problems related to irradiation damage in solid core materials by using a liquid fuel and coolant mixture. Technology pathways are maturing that can lead the way toward fulfilling the *full* promise of breed & burn, that of unlocking the massive energy content of depleted uranium without reprocessing.

Glossary

Actinides Eigen-composition Actinides composition which results from closed fuel cycle operation. It is specific and inherent for every reactor and it depends on its spectrum and feed type.

ALARA As Low As Reasonably Achievable.

ANL Argonne National Laboratory.

B&B Breed-and-Burn; a mode of operation that when at equilibrium, the core breeds fissile fuel in an un-enriched fuel feed and later fissions in-situ a fraction of the bred fuel without need for fuel reprocessing/recycling.

Breeding Converting a fertile isotope into a fissile one by capturing a neutron. Usually the fertile isotope ^{238}U to the fissile isotope ^{239}Pu . Also the fertile isotope ^{232}Th (natural thorium) to the fissile isotope ^{233}U .

Burnup A measure of the amount of fission energy released from a given mass of uranium (heavy metal). Unit is FIMA (Fissions per Initial Metal Atom; usually given in %) or Megawatt-days per kilogram (MWd/kg).

Cladding The structural material that separates the nuclear fuel from the coolant. In fast reactors it is usually made of steel.

DRACS Direct reactor auxiliary cooling system.

Excess reactivity When $K_{\text{eff}} > 1.0$, the core is said to have excess reactivity. Excess reactivity can provide a reserve at the beginning of the fuel cycle to compensate for fuel composition changes during the cycle. It has to be compensated at any given time to maintain a self-sustaining chain reaction.

FCS Functional containment system.

FPS Fission products.

HTGR High temperature gas cooled reactor.

IXC Ion exchange column.

LWR Light water reactor

MCFR Molten chloride fast reactor.

MSBR Molten salt breeder reactor.

MSFR Molten salt fast reactor.

MSR Molten salt reactor.

MSRE Molten salt reactor experiment.

Neutron economy Neutron economy term representing balance between neutron generation and neutron losses in a system. Good neutron economy has high neutron generation and small neutron losses by parasitic absorption in structural material and small leakage from the system.

PHX Primary heat exchanger.

Reactivity "Reactivity" denotes the extent of the deviation in the core effective multiplication factor (usually denoted as k_{eff}) from its value at a just critical state (at which state $k_{\text{eff}} = 1.0$ and the fission rate is constant). When ignoring the effect of

neutron leakage from the core, the neutron balance in the core is measured by the “infinite multiplication factor,” denoted as k_{∞} or k_{inf} .

RVACS Reactor vessel auxiliary cooling system.

SFR Sodium fast reactor.

Subcritical/critical core A core that cannot/can sustain a fission chain-reaction.

Temperature coefficient Relationship between fuel temperature and reactivity.

TWR[®] Traveling Wave Reactor; a solid fuel B&B reactor under development by Terra-Power.

XS Cross section; measures probability of neutron interaction.

Introduction

The Molten Chloride Fast Reactor (MCFR) is a type of Molten Salt Reactor (MSR) utilizing fuel in form of molten chloride salts. Accordingly, it shares many of the general MSR advantages and disadvantages listed in [Ignatiev \(2021\)](#). In theory, they can also be operated with a solid salt, which is occasionally re-melted and purified; the chloride salts can also act as a coolant in solid fuel reactor (e.g. [Taube and Schumacher, 1969](#)). These two options are not discussed here.

Chloride salt based concepts have been proposed already during the MSR pioneering time. At the end of the 1950s, the fluoride salt thorium thermal breeder was, nonetheless, considered as superior option with shorter doubling time. Accordingly, the past MCFR research was mainly based on supplementary theoretical concept studies. The historical experimental data for chlorides are also rather scarce compared to the fluorides as main research direction, which were studied in more detail ([Ignatiev, 2021](#)). In general, it seems that the melting temperatures for both salts are similar. For both salts additional studies are needed to address their corrosivity, compatibility with structural material, redox control, and many other safety and performance oriented parameters. Nonetheless, based on the Hard-Soft and Acids-Bases (HSAB) concept ([Pearson, 1968](#)), chlorine is generally a softer element than fluorine. This can cause issues with stability of chlorine compounds, redox control of the chlorides salt and with their corrosivity. The scarcity of experimental data is also the reason why this chapter focus on MCFR concepts overview and on major differences in neutronics and fuel cycle performance from fluoride based MSRs.

MCFR utilizes, similar to a fluoride based Molten Salt Fast Reactor (MSFR), a fast neutron spectrum to support in-situ fissile fuel breeding and/or utilization of the legacy used fuel. Whereas the MSFR spectrum features the softest fast spectra, the MCFR, due to the absence of moderator and moderating compounds like Be, Li, and F, ensures one of the hardest spectra of all fast reactors. It is common for fast reactors, including the MCFR and MSFR, for their neutron economy to be less sensitive to fission products buildup. This is caused primarily by the lower neutron capture cross-section (XS) of fission products in the fast spectrum, but also by the higher fraction of fissile isotopes in the fuel. In the actinides Eigen-composition ([Krepel and Losa, 2019](#)), which results from the repetitive fuel recycling, the share of fissile nuclides is typically above 10% of the heavy-metal (fuel) in fast reactors. This number does not differ strongly between U-Pu and Th-U cycle. For any thermal thorium breeder the fissile actinide fraction is below 2%. The importance of fission products in thermal spectrum is correspondingly higher. Since the thermal MSR is more sensitive to fission products buildup, aggressive online processing is often applied to counter the effects. Furthermore, because of the constrained neutron economy several thermal concepts rely on ²³³Pa (the precursor of the fissile ²³³U) separation to reduce its parasitic neutron absorption. For these reasons, thermal MSR breeders can only be operated with fluoride salts and low absorption moderators.

Several chloride salts envisioned for MCFRs can provide higher actinide fraction, at the respective melting temperature, as compared to fluoride salts of MSFR or a thermal MSR. The hard neutron spectrum and the related high neutron economy of the MCFR enables strong breeding in the Th-U and U-Pu closed cycles ([Hombourger, 2018](#)) or even operation in the open breed-and-burn U-Pu cycle, in which there is not a necessity to recycle the used fuel. This kind of self-sustaining cycle was first proposed by Feinberg and Kunegin ([Feinberg and Kunegin, 1958](#); [Kunegin and Feinberg, 2011](#)) and is reviewed by [Qvist \(2021\)](#). The possibility to operate breed-and-burn cycle with liquid fuel was pointed out in several publications, among the first being ([Hombourger et al., 2015, 2017, 2019](#); [Latkowski, 2015](#); [Kasam and Shwageraus, 2016, 2017](#); [Martin et al., 2017](#)). In this type of open fuel cycle, substantial fuel utilization can be achieved, as outlined in the dedicated breed-and-burn chapter ([Qvist, 2021](#)).

Recently, the MCFR concept based on chloride fuel salt, along with its breed-and-burn fuel cycle capability has garnered significant commercial interest and is currently under development by TerraPower, LLC (TerraPower[®]) ([Kramer, 2019](#); [Latkowski, 2019](#)). Their MCFR feasibility studies started before 2015, but were not published until 2015 and later ([Latkowski, 2015](#); [TerraPower, 2016](#)). This design is attractive, because the chloride salt offers a high uranium/transuranic solubility. It can be operated as a low-pressure compact system. Structural materials are absent in the core because it is unmoderated and the liquid molten salt fuel serves as the coolant. The breed-and-burn fuel cycle can provide high natural resources utilization without need of fuel enrichment and reprocessing or actinides separation, all of which are considered proliferation risks. As such, the MCFR concept distinguishes itself from other MSR concepts ([Ignatiev, 2021](#)).

As with other MSR concepts, the low-pressure nature of the MCFR and the high solubility of actinides and fission products reduces the driving force for reactor core source term release and makes passive decay heat removal possible, even with high power densities. During normal operation, part of the fission products (FPs), comprising an important part of the source term, can be

removed from the core via gas sparging and mechanical filtering. This will require safety attention and immobilization in engineered areas outside of the reactor core as mentioned in Ignatiev (2021). The fuel salt's large negative temperature coefficient and low excess reactivity, enabled by breed-and-burn operation or by continuous refueling, help ensure that overpower transients are not long lasting or run away. These characteristics coupled with the ability to passively remove decay heat prevent such transients from driving large temperature excursions.

Historical background

The history of the MCFR goes back to the beginning of the nuclear era. Some of the MCFR concepts belong to the family of homogeneous reactors. The aqueous homogeneous reactor from this family was the first reactor considered when the theoretical possibility of chain reaction was assessed in 1939 (Lane et al., 1958). Coincidentally, also in 1939, significant chlorine isotope separation was achieved (Beams and Skarstrom, 1939) by improving earlier established method (Beams and Haynes, 1936). The discovery of ^{239}Pu in 1940 as a ^{238}U transmutation product (Seaborg, 1994) opened new perspective and later resulted in a whole class of fast breeder reactors to which MCFR belongs. Around 1944, a Pressurized Water Reactor (PWR) concept was identified and patented (Wigner et al., 1945) and the term breeder was born (Weinberg, 1987). The design of first fast neutron breeder test reactor cooled by sodium was ongoing soon after (Zinn, 1946).

The MCFR concept was not considered in the period during and after the Manhattan project. Nonetheless, several properties of uranium chlorides were revisited and measured already within this project (Ginnings and Corruccini, 1947). Within the Aircraft Nuclear Propulsion (ANP) project (1947–61), at ORNL the attention moved towards higher temperatures and several additional reactor concepts were evaluated. In Ellis and Thompson (1950), melting temperatures of uranium chlorides are listed. However, other halides than fluorides were not considered for further research, because of their unfavorable neutronic properties. This could be related to the requirement of compact cores for the nuclear-powered jets. In later ANP reports, fast reactors were, in general, excluded because of the potential reactivity control problem caused by the shorter neutron lifetime (Fraas and Savolainen, 1954). When the ANP program was finished, ORNL decided to develop MSR for civilian applications. The graphite moderated thorium breeder Molten Salt Breeder Reactor (MSBR) was chosen for several reasons, the major ones being low fissile inventory, short doubling time, high thermal inertia and appealing Th-U fuel cycle (Briant and Weinberg, 1957). The chlorides were recognized from neutronic perspective as suitable for fast reactors. The need of ^{37}Cl enrichment was perceived as more difficult than the ^7Li enrichment for fluoride salt. Another considered weakness of the MCFR was the large fissile fuel inventory and the related longer doubling time of decades. Also MSFR was excluded because of the longer doubling time and so MSBR was chosen, at that time, as a major research direction with strong experimental support.

Around 1952–53 a group of students at the Oak Ridge School Of Reactor Technology (ORSORT) started designing fused salt fast breeder reactor based on fluoride salts and the Th-U cycle (Wehmeyer et al., 1953). It is a predecessor of the MSFR design. At the same time, a nuclear engineering project at M.I.T. was dedicated to non-aqueous liquid fuels for the U-Pu cycle (Goodman et al., 1952). The resulting MCFR concept was based on homogeneous core surrounded by reflector and blanket. Argonne national laboratory compiled a report (Glassner, 1953) with thermochemical properties of the chlorides up to 2500 K, which was later updated (Glassner, 1957). In 1954 it was followed by a UK report, which was declassified in 1957 (Bradley, 1957) and dedicated to chlorides of actinides and fission products. Interestingly, thorium chloride was included in all these reports. From 1957, there is also one Russian report with chlorides properties (Belyaev et al., 1957). In 1955 and 1956, another two groups of students at ORSORT considered chlorides as immiscible direct coolant for liquid fueled reactor (Burch et al., 1955) and as homogeneous two-fluid MCFR (Bulmer et al., 1956), respectively. In 1958, the *Fluid Fuel Reactors* book (Lane et al., 1958) was published, where one third was dedicated to MSRs. The MCFR concept is not mentioned in this book. In 1959, ORNL published a report with phase diagrams of several fluoride and chloride binary mixtures (Thoma, 1959).

During the 1960s, the majority of the above reports were publicly available and chloride salts were proposed also for pyro-reprocessing (Harder et al., 1969). In 1962, a cooperation agreement was signed between USAEC and EURATOM which covered also MSR (EURATOM, 1963). In 1963, there was a conference on breeding, economics, and safety in large fast power reactors at ANL (Okrent, 1963) with one MCFR contribution (Alexander, 1963). Around this time, the chloride salts as a potential fuel or fuel reprocessing medium were recognized also in other countries, e.g., Poland (Taube, 1961) and later Switzerland (Taube and Ligou, 1972), Germany (Naumann, 1962), and the United Kingdom (Moore and Fawcett, 1966). In 1969, there was a symposium on reprocessing of nuclear fuels at Iowa State University (Chiotti, 1969), where pyro-chemical methods based on chlorides were presented also by scientists from Japan and India. There was some research dedicated to chloride salt properties in Russia (Desyatnik et al., 1970). Nonetheless, the research in Russia, Japan, India, Germany (Vornhusen, 1965) and France (Hery and Lecocq, 1984) was oriented rather on fluorides salts.

Neutronics characteristics of chloride salts

Compared to fluorine, which has only one stable isotope ^{19}F , chlorine has two stable isotopes ^{35}Cl 76% and ^{37}Cl 24%. The ^{35}Cl capture XS is significantly higher than that of ^{37}Cl (see Fig. 1); even though, there is some difference between the XS libraries' values. Therefore, in order to reduce the parasitic neutron capture in chlorine and thus improve the neutron economy, a majority of MCFR

Fig. 1 Neutron capture XS of selected isotopes from ENDF/B-VII.0 XSs library.

Fig. 2 Neutron scattering XS of selected isotopes from ENDF/B-VII.0 XSs library.

designs assume isotopic enrichment and application of nearly pure ^{37}Cl . This is very similar to the situation with ^6Li (92% of Li) and ^7Li (8%) isotopes where many MSFR and MSBR concepts rely on enriched ^7Li . In both cases the enrichment not only increases the neutron economy, but also reduces the production of radioactive daughter products. Capture XSs of ^{37}Cl and ^{23}Na have similar nature and amplitude. They are more than one order of magnitude higher in the thermal spectrum (below ~ 1 eV) than XSs of ^7Li , ^9Be and ^{19}F , but similar to ^1H capture. In general, the isotopes ^1H , ^{23}Na and ^{37}Cl can be applied for thermal reactors; however, their higher capture burden will prevent a self-sustaining breeding in the Th-U cycle. In the U-Pu cycle, the equilibrium actinides Eigen-composition alone prevents the self-sustaining breeding practically in all thermal reactors (Krepel and Losa, 2019). The data presented in Figs. 1 and 2 are adopted from ENDF/B-VII.0 XSs library.

The second most relevant neutronic parameter is the scattering XS. From this perspective, ^{37}Cl behaves rather like ^7Li than as ^{23}Na and has a quite low scattering XS. It is much lower than the scattering XSs of ^{19}F and ^{23}Na for neutron energies below 1 keV. Furthermore, slowing-down properties of an isotope depend also on the average logarithmic energy decrement imparted during a neutron scattering interaction. This decrement can be used to enumerate number of required collisions to reduce the neutron energy, for instance, from 2 MeV to 1 eV. Since ^{37}Cl is the heaviest isotope in this discussion, it needs the highest number of collisions ~ 273 to slow down a neutron to 1 eV (see Fig. 2). The same number for ^7Li is 56. Furthermore, ^7Li has quite broad resonance around 260 keV. This is also the reason, why homogeneous MSFR with $^7\text{LiF-BeF}_2$ carrier salt was considered as moderated reactor during the MSBR project at ORNL. Even if BeF_2 is omitted and solely ^7LiF carrier salt is used, the fast MSFR spectrum is still very soft. On the other hand, MCFR based on a Na^{37}Cl carrier salt provides one of the hardest neutron spectra possible. Harder spectra can be obtained only with actinide chlorides omitting ^{23}Na , or with molten metallic actinide slurries. The discussion of available chloride carrier salts with limited moderation was thoroughly done in Taube (1961) considering also other criteria. As most suitable compounds Na, K, Mg, Ca and eventually CuCl (CuCl_2) and ZnCl_2 were identified. In the TerraPower patent (TerraPower, 2016) also BaCl_2 , SrCl_2 , VCl_3 , CrCl_3 , TiCl_4 and ZrCl_4 are listed together with the mixture of chloride and fluoride salts.

The neutronic properties of ^{37}Cl provide very hard neutron spectrum and very low parasitic neutron absorption. The actinides' Eigen-composition of equilibrium Th-U and U-Pu cycles in such spectrum results in a very high neutron economy (Krepel and Losa, 2019) and thus enables new fissile fuel breeding and/or utilization of legacy used fuel. At the same time, the absence of strong scattering and capture reaction rates has a consequence in very large neutron mean free path (average distance a neutron travels until it collides). A typical homogeneous MCFR core is transparent for neutrons and thus leaky. With high associated neutron leakage, the need of reflector or blanket is more pronounced in MCFR than in MSFR. It is also the reason, why salts with high actinides fraction are considered for MCFR.

Historical and current MCFR concepts

MCFR designs can be generally divided into homogeneous and heterogeneous reactors. In the (Goodman et al., 1952 and Bulmer et al., 1956) reports the external and internal cooling option is discussed. It is practically a synonym for homogeneous (external cooling) or heterogeneous (internal cooling) core geometry. The advantage of external cooling is that the parasitic capture of structural materials and coolant in the core is minimal. At the same time, the fuel salt acts as a coolant and must be pumped to the external heat exchanger. This layout increases fissile fuel inventory and results in delayed neutrons loss in primary circuit. The necessary salt volume can be optionally reduced by integral core design, where volume of piping and size of the heat exchangers is minimized. The advantage of internal cooling, on the other hand, is that the salt does not need to be pumped out of the core for the cooling purpose. Presence of the dedicated coolant and separating structural materials in the heterogeneous core, however, deteriorates the neutron economy by softening of the neutron spectrum and increasing parasitic neutron absorption. Many of these concepts rely on metallic tubes with very thin walls, profiting from the low pressure difference, or on SiC tubes, because of its low parasitic capture.

The advantages of homogeneous and heterogeneous core geometry can be combined in the directly cooled MCFRs. In (Burch et al., 1955) direct cooling of the liquid fuel, based on uranium solution in molten bismuth, was considered by an immiscible coolant (KCl-LiCl). In this internal cooling case, the structural material can be avoided and liquid fuel circulates only within the core. The largest drawback of the directly cooled MCFRs is the materials exchange between the fuel and coolant. An extreme direct cooling option is represented by boiling coolant salt (Taube et al., 1967). Based on the terminology from several reports, e.g. (Smith et al., 1974 or Taube, 1977), three types of MCFR concepts can be identified depending on heat exchange properties. These types are labeled here as:

1. Homogeneous MCFR: externally indirectly cooled
2. Heterogeneous MCFR: internally indirectly cooled
3. Directly cooled MCFR: internally or externally directly cooled

Since the third option, direct cooled reactors, is rather exotic, the MCFR can be generally divided into heterogeneous and homogeneous concepts. The MCFR designs can be further classified as with other MSRs by number of actinides-containing salts including one-fluid, two-fluid or multi-fluid options. As with any other reactors, MCFRs can be also classified by purpose as burner, converter, or breeder operated in open or closed Th-U or U-Pu cycle. Very particular is the breed-and-burn operation mode.

Breed-and-burn cycle in MCFR

Breed-and-burn cycle is a special type of open fuel cycle, where substantial fuel utilization can be achieved, as outlined in the dedicated breed-and-burn chapter (Qvist, 2021). Both, homogeneous (Hombourger et al., 2015, 2017, 2019; Latkowski, 2015; Martin et al., 2017) and heterogeneous (Kasam and Shwageraus, 2016, 2017; Kasam et al., 2020; Cuoc et al., 2020). MCFR have a potential to be operated in breed-and-burn cycle. Nonetheless, the neutron economy is tighter in heterogeneous MCFR.

There is substantial difference between liquid-fuel and solid-fuel reactors operating in the breed-and-burn cycle. In both cases, the fresh fuel used for repetitive refueling of the reactor consists only of fertile material, which is either natural or depleted uranium. In the solid-fuel reactor, the highest-burnup fuel is discharged from the reactor and the average content of fissile material makes the core critical, even though the fresh fuel has nearly zero fraction of fissile material (see Fig. 3). On the other hand, in case of single-fluid MCFR, the fuel is homogenized in the reactor and the discarded fuel has the average burnup (see Fig. 4). As a consequence, the discharged fuel can be accumulated and later used to start daughter breed-and-burn MCFR. To achieve higher burnup or to reduce slightly the core size, multi-fluid MCFR layout can be applied (see Fig. 5). In this case, the molten-salt in the outermost annulus acts as a blanket (Raffuzzi and Krepel, 2020) and the discharged fuel, typically from the inner core zone, will have higher than average burnup and it may not be used to start another breed-and-burn MCFR.

The performance of a breed-and-burn reactor can be assessed by neutron balance concept, which is discussed in (Qvist, 2021). This concept is applicable also to MCFR. Nonetheless, there is one major difference caused by liquid fuel homogenization. The burnup and composition of a single solid fuel assembly is evolving according to the local flux, but independently from the other assemblies. At the end of irradiation, it is discharged from the core at maximal burnup. In case of liquid fuel, the fuel at different stages of burnup is mixed together. Hence, the discharged fuel has an average burnup and composition. The composition can be simulated by averaging over the residence time distribution (Hombourger et al., 2019). Fig. 6 illustrates the impact of the fuel mixing on the neutron balance evolution. The example was obtained for 68%Na ^{37}Cl -32%U $^{37}\text{Cl}_3$ salt, which was treated in two

independent cell-level simulations as a liquid and as a solid fuel, respectively. In both cases, the specific power of the MSFR design $\sim 300 \text{ W/cm}^3$ was adopted. This value can be too high for large MCFR cores. Nonetheless, the dependence of the U-Pu cycle performance on the specific power is much milder than for the Th-U cycle (Krepel and Losa, 2019). Hence, the curves will not change significantly for lower specific power.

Fig. 6 shows that in liquid fuel reactor, the neutron excess curve becomes positive for much higher burnup than in solid fuel reactors. It has a lower maximum and flatter decline. For more detailed discussion about the important points of the neutron excess curve and their meaning refer to (Qvist, 2021). The maximal infinite neutron multiplication factor k_{inf} of the liquid fuel reactor is achieved at burnup around 30–40% FIMA. In solid fuel reactor, the curve is peaking earlier and at higher values. Since each refueling rate in liquid fuel reactor results in specific discharge burnup, the neutron excess and the related k_{inf} are, actually, a function of the refueling rate. The maximal k_{inf} is obtained for refueling rate corresponding roughly to 3% per year. Nonetheless, the position of k_{inf} maximum slightly differs between different salt compositions (see left Fig. 7). The k_{inf} curve for liquid fuel reactor in Fig. 6 and left Fig. 7 is rather symmetric with burnup. Similar curve as in (Hombourger et al., 2019) can be found also in (Martin et al., 2017) or (Raffuzzi and Krepel, 2020).

The minimal and maximal burnup, which allows for MCFR operation in the breed-and burn mode, depends on the k_{inf} curve and on the core size, which determines the neutron leakage and so the relationship between k_{inf} and k_{eff} . Hence, in the actual MCFR design, core size as one design parameter directly competes with the fuel burnup. From neutron balance perspective, the burnup, in the cases with very high uranium concentration in the salt, may be as high as 55% FIMA. The minimal MCFR burnup, necessary for breed-and burn mode of operation, is around 20–25% FIMA.

Based on the maximal k_{inf} values from left Fig. 7, the minimum dimensions of reflected single-fluid MCFR cores as estimated by Hombourger et al. (2019) are given in right Fig. 7. These core volumes are quite large: $\sim 50 \text{ m}^3$ for salts with very high actinides share and $\sim 100 \text{ m}^3$ for more realistic salt without UCl_4 . If the core is to deliver a thermal power of 5000 MW, as of the largest commercial light-water-reactor, the respective specific power needs to be 100 and 50 W/cm^3 . This power density is lower than the 300 W/cm^3 assumed in the calculations the results of which are reported in Figs. 6 and 7. However, Martin et al. (2017) are reporting that k_{inf} slightly increases as the assumed power density is lower implying that it might be possible to slightly reduce the Fig. 7 reported core volumes. The actinides inventory in the respective cores is slightly less than ~ 100 tons and ~ 120 tons. Accounting for the salt volume outside of the core (circulating through the heat exchangers) the overall inventory will be even higher. The specific actinides inventory of the example core power is, respectively, $> 20 \text{ kg/MW}_{th}$ and $> 24 \text{ kg/MW}_{th}$. These are to be compared with $> 17 \text{ kg/MW}_{th}$ in conventional solid-fuel liquid-metal cooled reactors and $\sim 24 \text{ kg/MW}_{th}$ in commercial pressurized water reactors.

The initial loading of a breed-and-burn MCFR core can be either enriched uranium or Trans-uranic elements recycled from existing used nuclear fuel. In both cases, the fissile fuel inventory in the initial fuel is around 10–12% (Hombourger et al., 2019). The TerraPower MCFR design, described in this chapter as a reference, will be started by enriched uranium and achieves burnup of 20% FIMA with an 1800 MW_{th} design over 60 years if employing a once through fuel cycle. After this initial cycle, the reactor could continue operations in breed-and-burn cycle beyond 60 years with irradiated fuel used to support daughter reactors.

The discharged burnup in a natural (or depleted) uranium fed breed-and-burn core is, after reaching equilibrium composition, the natural uranium utilization. Accordingly, breed-and-burn MCFR might achieve a very high uranium utilization of $\sim 35\%$. This is ~ 60 times the utilization of natural uranium in contemporary light water reactors; both operating in a once-through fuel cycle. In a solid fuel breed-and-burn reactors the discharge burnup is limited by radiation damage to the fuel cladding to less than $\sim 20\%$ FIMA (Qvist, 2021; Hejzlar, 2021). The molten salt, as an ionic liquid, is not constrained by the radiation damage. What is

Fig. 7 Evolution of k_{inf} (left) and minimum core size (right) dependence on the salt composition; the dimensions pertain to the peak k_{inf} FIMA. From Hombourger B, Krepel J, and Pautz A (2019) Breed-and-burn fuel cycle in molten salt reactors, progress in the science and technology of nuclear reactors using molten salts. *EPJ Nuclear Sciences & Technologies* 5.

challenging the MCFR design are: (1) finding a fuel salt mixture which allows for high actinides and FPs concentration and, at the same time, has suitable chemical and physical properties, (2) fast neutron induced radiation damage to the core vessel and (3) the large volume required for the core.

Directly cooled MCFR

Molten salts are limited as coolants due to the poor heat transfer properties. Compared to liquid metals their thermal conductivity is very low (typically 0.1–0.6 W/mK) and rather comparable to water. Hence, large heat-exchange surface is usually needed. The idea of liquid fuel cooling by direct contact with salt coolant liquid was presented in Burch et al. (1955) where uranium solution in molten bismuth was cooled by KCl–LiCl. This solution may reduce the fissile fuel inventory. The heat exchangers can be designed for the cooling medium and not for the fuel. However, the coolant will be strongly contaminated by the direct contact with fuel. As mentioned by Taube (1977) this is extremely exotic reactor type. Since there are not many concepts in this category, few non-chloride designs with fluoride salts or metallic fuels are also included. The overview of the concepts is shown in Table 1 and Fig. 8.

Heterogeneous MCFR

The basic characteristics of heterogeneous MCFR concepts is that the primary heat exchange between the fuel salt and coolant take place in the active core. The material separating these fluids must be compatible with both of them and withstand strong neutron irradiation and high temperatures. Furthermore, it should not have high neutron capture XS, which would deteriorate the neutron economy. Since the pressure difference between the liquids may be low, thin metallic tubes are proposed to minimize the neutron absorption. Other proposed option with low neutron capture XS is SiC.

The heterogeneous MCFR acts to a certain extent as a reactor with solid fuel. Hence, it must rely on heat conduction by fluid coolant. Furthermore, the heat removal from the active core is proportional to the heat-exchange surface area. Accordingly, the power rating and core size are tightly linked together as for solid fuel reactors. This link does not exist for homogeneous MCFRs, where the heat can be conducted directly by the fuel and the core size is limited rather by neutronic constraints or by thermal properties of the surrounding solid materials. The heterogeneous MCFR concepts overview is presented in Table 2 and Fig. 9.

Homogeneous MCFR

One major advantage of a homogeneous MCFR is that the core zone is filled solely by the fuel salt, which acts simultaneously as a coolant. In opposite to heterogeneous MCFR, where the core power depends on heat exchange surface in the core, in homogeneous MCFRs the heat is released directly in the circulating salt. The power of the MCFR is thus limited rather by thermal-hydraulics and thermal-mechanics constraints. The typical power considered for MCFR is 3GW_{th} .

The homogeneous MCFR concepts tend to have superior neutronic economy. At the same time, the fuel salt, as a coolant, must be pumped to the primary heat exchangers. The salt volume outside of the core is thus substantial and the actinides load is usually high. The necessary salt volume can be optionally reduced by integral core design. The superior neutronic economy enables operation in breed-and-burn fuel cycle. Nonetheless, it is still needed to minimize neutron leakage, hence the breed-and-burn MCFRs are usually large. Accordingly, they would be capable to produce much higher power than 3GW_{th} . The homogeneous MCFR concepts overview is presented in Table 3 and Fig. 10.

Representative current MCFR development

One currently proposed MCFR concept under TerraPower, LLC commercial development utilizes a breed-and-burn approach based upon the uranium-plutonium fuel cycle (Kramer, 2019). This MCFR core is well-mixed because all the fuel salt is fully circulating about once per second. This design utilizes a potential breed-and-burn fuel cycle is illustrated in **Fig. 11**. Following initial start-up with enriched ($\sim 12\%$ ^{235}U) fuel, this MCFR design does not require ongoing fissile material makeup. Instead, an MCFR can be fed by depleted or natural uranium. During normal operations, the reactor reactivity tends to slowly increase as a result of a neutron conversion ratio exceeding 1. To counter this increase in reactivity, a small quantity of fully mixed fuel salt is removed and replaced with fertile feed salt. The addition of fertile material acts, in effect, as a burnable poison that reduces reactivity.

This MCFR does not require enriched fissile material following its initial charge.

Fig. 11 Graphical depiction of the proposed breed-and-burn fuel cycle with irradiated fuel from an MCFR stored for future use in daughter plants (without reprocessing) or sent to waste for disposal.

Table 4 Summary of operational and fuel cycle characteristics of LWRs, MCFRs and other advanced reactors.

Characteristic	LWRs	SFRs	HTGRs	Other MSRs	MCFR
Online refueling	No	No	Possible with pebbles	Yes	Yes
Fuel shuffling avoided	No	No	No	Yes	Yes
Fuel processing avoided	Yes	No (except TWR [®])	Yes	Online	Yes
Breed-and-burn variant	No	No (except TWR [®])	No	No	Yes

Rather than going to disposal, used MCFR fuel can be collected and stored in a critically safe geometry until a sufficient amount is available to start a new reactor. As this fuel was accumulated from an operating reactor, it should contain sufficient fissile material to support initial critical operations of a second generation reactor. These daughter reactors utilizing this fuel salt will be able to start up without any new enriched feed fuel (see Fig. 11). By transferring used fuel, in total, to a daughter plant, this MCFR significantly reduces the use of actinides and defers the need to dispose of the vast majority of radioactive waste until the end of fleet build-out. For ultimate disposal of actinide-bearing fuel salt, prior work found that the salt itself could be packaged, without chemical conversion, into a suitable waste form (Toth et al., 1993). This and additional waste forms requires further research and development.

The open breed-and-burn fuel cycle supported by the breed-and-burn MCFR can result in lower volumes of waste than a conventional open fuel cycle due to higher potential burnup and lack of structural material being part of the waste.

During normal operations, it is likely that MCFR fuel salt will receive some cleanup or polishing including mechanical filtering of the noble metals and removal of noble gases to improve neutron economy. Polishing is defined as mechanical filtering and inert gas sparging to remove volatile fission products, while avoiding electrochemical separations. This fuel polishing is a feature of MSRs in general and can coexist with online refueling. The MCFR can similarly avoid fuel shuffling to support breed and burn as the fuel salt is continuously mixed. For a comparison of these features for different reactor types, refer to Table 4. A thermal spectrum MSR has substantial in-core surface area for gas accumulation. This potential for gas accumulation coupled with a large thermal neutron capture XS of xenon requires aggressive fission gas removal to maintain system criticality. In contrast, the lack of a moderator and the lack of in-core structure in an MCFR greatly limits surface area for gas accumulation. Similarly, the fast neutron spectrum limits the reactivity worth of these gases due to lower capture XS at higher neutron energies. These two combined factors allow for less aggressive gas removal. These polishing operations have the potential to produce a stream of nearly pure fission products. Since this stream will contain only trace quantities of actinides, it is possible to consider processing this material and isolating the long-lived fission products for simplified handling of the resulting waste. Fluoride fuel salt waste forms have been discussed in the literature (Toth et al., 1993); these may be applicable to chloride fuel salts and fission products as well.

Operationally and economically, the MCFR could perform well due to inherent simplicity. The low pressure and high boiling point of the fuel salt avoids the need for thick-walled, expensive forgings and reactor components. The high solubility of actinides in the salt and high volumetric heat capacity of the salt enables a high core power density, thereby potentially reducing capital

requirements. Molten salt fueled reactors can, in general, support online refueling due to the liquid fuel form. With online refueling, plant availability can be enhanced driving overall economics in a positive direction. The avoidance of online reprocessing also arguably increases proliferation resistance, reduces capital costs, and increases reliability (with a reduced requirement for complex processing trains) and availability (by reducing outage requirements). Additionally, the MCFR like other MSR designs requires relatively inexpensive fuel synthesis rather than complex high tolerance fuel fabrication of hundreds of kilometers of fuel pins, cladding, and coatings. MSR's can support high temperature operation because the fuel is already molten and a large margin exists at operating temperatures relative to the fuel salt boiling point. Existing MCFR designs typically employ a core outlet temperatures $> 700^{\circ}\text{C}$, but can be even higher with advanced high-temperature materials like refractory alloys. This high temperature operation can provide a high thermal efficiency ($> 42\%$) when coupled to a commercially-available steam cycle equipment. All of these factors combine to provide the potential for simplified operations and maintenance and improved economics.

Table 5 provides a summary of these and other safety features that together distinguish the MCFR from present LWR technology and other proposed non-LWR advanced reactors. In addition to providing the basis for defense in depth safety strategies, many of these features also contribute to operations and economic performance.

Technical description

The MCFR under development by TerraPower, LLC is of homogeneous type and uses a salt mixture composed of various sodium chloride and uranium chloride components. An example ternary phase diagram for this family of salts is shown in [Fig. 12 \(Cisneros et al., 2019\)](#). The blue shaded region shows the extent of a representative 500°C melting envelope. Multiple fuel salt compositions

Table 5 A summary of key safety characteristics of LWRs, the MCFR, and other advanced reactors.

Characteristic	LWRs	SFRs	HTGRs	Other MSRs	MCFR
Chemical reactivity	Steam reacts with the cladding to produce H_2 gas	Steam/water exothermically react with liquid sodium	Graphite can burn in air (MIT, 2018)	If using graphite, graphite can burn in air	Limited/slow reaction of salt with O_2 , soluble in water
Nuclear reactivity	Excess reactivity to provide 18–24 month cycle	Slight excess reactivity to provide economic cycle	Excess reactivity to provide economic cycle	Near-zero excess reactivity	Near-zero excess reactivity
Pressure	High pressure	Low pressure	High pressure	Low pressure	Low pressure
Temperature coefficients	Overall negative	Overall negative	Overall negative	Strongly negative, overall negative if using graphite	Strongly negative
Decay heat removal	Gen 2 active, very limited; Gen 3+ limited but passive	Passive	Passive, cause significant power density limitation	Passive	Passive

Fig. 12 The ternary phase diagram for UCl_3 - UCl_4 - NaCl in mole % ([Desyatnik et al., 1971](#)).

can be considered and should be capable of net breed-and-burn behavior with final composition being determined by a variety of factors including corrosion, solubility, viscosity, and reactor size.

Liquid fuels have an inherent advantage over solid fuels in that a solid fuel must first conduct heat to the outer surface of the fuel element, next conduct heat through the cladding (including past a physical gap or through a bond material), then convect the heat from the cladding surface to the primary coolant, and finally advect the heat out of the core. By comparison, a liquid fuel can directly transport the fuel salt/primary coolant out of the core and to the primary heat exchanger. Whereas there is up to 1000 °C difference between the maximum fuel temperature and coolant outlet temperature in the solid fuel reactor; in a homogeneous MCFR the highest fuel temperature is equal to the salt outlet temperature. Additionally, the liquid salts have volumetric heat capacities that are nearly twice that of liquid sodium at similar temperatures.

Another key advantage provided by a fuel salt is a strong and prompt negative temperature coefficient. Due to temperature dependent density changes, the MCFR core with hot fuel salt has a lower reactivity than core with cold salt. As a result, transients that result in increased heating are limited in severity by the expansion of the fuel salt. As the chloride salt is heated from 600 to 800 °C, its density drops significantly. This inherent feature provides a negative reactivity feedback that is much stronger than that provided by the Doppler effect.

Fig. 13 shows a view of a potential MCFR design. In addition to the vessel, the figure shows the flow path for the fuel salt (red dashed lines) and the neutron reflector (gray regions). In this concept, fuel salt flows up through the center of the core, flows past the upper axial reflector, and enters one of the pump assemblies. Upon exiting a pump assembly, the fuel salt immediately enters one of the primary heat exchangers (PHX).

Materials survival is an ever-present challenge to technology readiness for molten salt reactor concepts. In response, MCFR candidate materials are being tested early in non-nuclear environments such as flow loops at TerraPower, LLC and the MCFR can be designed for modular replacement of key components. Molten salt corrosion dictates the use of advanced materials, such as refractory alloys, for fuel salt-facing components, such as reflectors, primary heat exchangers (PHX) and the vessel. However, components only need to be clad or coated using these advanced materials, while the bulk of such component structural material can be constructed from more traditional materials. Radiation damage is also a factor for structural material survivability and component replacement intervals will be defined by those radiation damage limits like a solid fueled reactor. However, in a molten salt reactor, that radiation damage lifetime will likely be set by the first structural wall nearest to the high radiation flux center of the core as opposed to fuel or cladding limits in solid fueled reactors.

The MCFR reactor vessel and reactor head can utilize relatively thin plate due to the low normal and low design basis pressures.

Fig. 13 The MCFR modular design for the reflectors and primary heat exchangers.

Operational, safety and public acceptance features

The MCFR design lends itself to simplified operations and maintenance. The fact that the fuel salt is non-chemically reactive and at low pressure leads to significantly simpler operations and maintenance. Similarly, the fact that the fuel salt is molten ensures “continuous shuffling” or mixing of the fuel and no mechanical fuel shuffling system is required. This has the potential to significantly improve plant availability and minimize downtime. Maintenance of some systems can be performed online, while others will require draining of the fuel to storage tanks. The drained reactor core will consist of modular components that can be directly accessed and removed via remote handling once the vessel head is removed. Internal core components, vessel and head, and support structures can be inspected as well.

Decay heat removal can be accomplished by natural convection through one or more primary heat exchangers, out through a naturally-circulating intermediate loop, and passively dumped to air heat exchangers. Typically, this is accomplished in concert with reactivity shutdown systems as the negative temperature reactivity coefficient of the fuel salt will lead to increased reactivity as the decay heat system eventually lowers the fuel salt temperature. Multiple options exist for reactivity control including fuel displacement, control rods, or control drums. This simplified approach reduces the number of additional systems for passive decay heat removal under anticipated operational occurrences and design basis accidents. This can all be accomplished entirely via natural convection and without any site power.

As part of the TerraPower approach to include multiple fission product barriers, MCFR's can readily employ a Functional Containment System (FCS) as proposed in INL/EXT-14-31179 (Idaho National Laboratory, 2014). Per this definition, a FCS will serve as “a barrier, or set of barriers taken together, that effectively limit the physical transport and release of radionuclides to the environment across a full range of normal operating conditions, anticipated operational occurrences, and accident conditions. Functional containment is relied upon to ensure that dose at the site boundary as a consequence of postulated accidents meets regulatory limits.”

In an MCFR, a developer could consider a FCS to be comprised of the Fuel Barrier, the Containment Structure, and the Reactor Building. The Fuel Barrier is the first barrier against uncontrolled release of radionuclides. It is comprised of corrosion resistant cladding on reactor vessel plate, piping, primary heat exchanger tubing and tube sheets and is designed to withstand design basis pressures.

The containment structure is likely a high temperature alloy lined reinforced concrete building structure and includes equipment and personnel hatches, process piping penetrations through the building with isolation valves, and expansion joints to allow differential movement between penetrating process piping and the building structure. During normal operation and maintenance, the containment structure would be kept at a slightly negative pressure, and during operation it is back filled with an inert gas. The containment structure will be designed and constructed to the applicable portions of ASME Boiler and Pressure Vessel Code to assure that it reliably performs its safety related functions.

If the fuel barrier were to leak, the containment structure is designed as the second barrier to uncontrolled release of radionuclides. The containment structure includes passive over pressure protection and when actuated, vents through filters to the reactor building, which has sufficient passive cooling.

The reactor building is likely the third barrier against uncontrolled release of radionuclides. The reactor building will have a ventilation system which circulates and monitors the atmosphere and is equipped with a filtration system to process normal effluents as well as limit the release of radionuclides during all anticipated operational occurrences and design basis accidents.

The combination of the multiple barriers would comprise the FCS and will be designed to limit radiation exposure to operational personnel and the public to within the applicable regulatory limits during operation as well as during and after postulated design basis accidents and to maintain any such exposures as low as reasonable achievable (ALARA), in accordance with national and international standards.

The FCS provides radiation shielding for the reactor core and associated equipment and provides protection from internal and external missiles to assure that the FCS can reliably perform its designed functions.

In addition, the containment and reactor building can be sized such that over pressurization cannot occur. Due to the fact that the molten salt fuel is non-reactive (even at high temperatures) and the reactor is normally operated at low pressures, thereby preventing a number of the driving forces by which a source term can be mobilized.

The MCFR employs multiple passive features that enhance safety. Modular components do have to be periodically replaced via remotely handled equipment. These remote handling systems can be continuously monitored to enhance safeguards. Similarly, the infrequent nature of reactor core component replacement yields infrequent and very controlled entering of containment. In the breed-and-burn MCFR design, fuel is moved to safe storage when any maintenance is performed, and these storage systems can be incorporated into material accountability systems.

Safeguards and non-proliferation

In contrast to other reactor designs, MCFR fuel design makes use of a high-actinide content chloride salt. Additionally, the MCFR performance improves significantly with chlorine that is enriched to at least 75% ^{37}Cl . The use of enriched chlorine reduces both neutron parasitic absorption and production of ^{36}Cl , which is a long-lived activation product. Chlorine enrichment is not available today from commercial sources, but either centrifugal or ion exchange column (IXC) methods of enrichment appear viable and extensible to the required quantities (Holcomb et al., 2011).

With its potential avoidance of reprocessing and ability to operate without fissile feed material after initial start-up, the MCFR offers an improved proliferation resistance among MSRs. Additional non-proliferation advantages are realized due to the near-zero excess reactivity. Removal of fuel salt beyond that required for online refueling would be a detectable event as the fuel salt contains multiple fission products producing significant dose. Similarly, removal of fuel salt beyond the designed volume would result in the reactor entering a subcritical configuration. The reactor could not start back up without addition of more enriched fuel. As a result, the MCFR does not require pyroprocessing, electrochemistry, or other separative online reprocessing technologies that raise potential proliferation concerns.

Used MCFR fuel salt will contain plutonium chloride and other transuranics, but these are fully mixed with uranium and chemically similar lanthanide chlorides (from fission products). Early material attractiveness analyses utilizing a Figure of Merit approach, which was originally developed by Bathke et al. (2012) for other fuel cycles, have been applied to the MCFR. These analyses indicate that MCFR used nuclear fuel could be less attractive than that from a fluoride molten salt from which lanthanides have been separated. A summary of some key proliferation characteristics are outlined in Table 6.

Economic competitiveness

The MCFR concept has the potential to simplify some operations and maintenance, potentially improving economic competitiveness. The fact that the fuel salt is non-reactive, transparent and at low pressure leads to significantly simpler operations and maintenance and lower operating costs. However, those operations and maintenance must be performed using remote handling, which must be further developed. Maintenance of many systems can be performed online, while others require draining of the fuel to storage tanks. Internal core components, vessel and head, and support structures can be inspected or replaced after fuel is drained to storage tanks. The steam generators can be located outside of primary containment to allow for maintenance without full shut-down of the core. With the exception of remote handling, these operational aspects of an MCFR have the potential to positively impact overall plant economics.

Typical MCFR waste streams are unlike conventional light water reactor waste streams. It has two components, one is the actual discharged fuel with all the actinides, the second are the separated fission products. The most prominent aspect is that these fission products contain only trace actinides. The MCFR fission product waste can be separated from unburned uranium or other actinides. This waste is proposed to be captured through mechanical filtering and gas sparging. Similarly, noble fission product gasses can be captured and allowed to decay in holding tanks. The filters containing the insoluble and longer lived fission products form a portion of the waste stream. This waste also has the benefit of minimizing criticality concerns as there are few fissile isotopes separated from the fuel salt.

Reactor core components and structures that are periodically replaced, assuming a modular design, will need to be cleaned of fuel salt and mechanically packaged for waste disposal. These components become activated from their presence in the reactor core. However, the chlorine (Cl) in the MCFR salt does produce a concern if it is placed in a geologic repository, activated ^{36}Cl is a radionuclide of concern in the performance assessment of such facilities (Croff and Krahn, 2015); this concern is mitigated, to a degree, by using Cl that is enriched in ^{37}Cl , but not eliminated.

Summary and path forward

MCFRs belong to the family of liquid-fuel molten salt reactors and utilize chloride salts containing actinides as a liquid fuel. MCFRs can be generally subdivided into homogeneous and heterogeneous concepts, based on the core structure. The neutronic properties of chlorine and especially of its isotope ^{37}Cl provide a very hard neutron spectrum and very low parasitic neutron absorption. The resulting very high neutron economy can be used for new fuel breeding or legacy waste burning. At the same time, the low scattering and capture XS has consequence in very high neutron leakage probability. Typical homogeneous MCFR must thus rely on efficient reflector and/or blanket and bulky core. It has also implication on possible doubling time for both open breed-and-burn and closed fuel cycles.

The homogeneous and heterogeneous categories are practically synonyms for internal and external cooled reactors. The advantage of external cooling is that the parasitic capture of structural materials and coolant in the core is minimal. At the same time, the

Table 6 A summary of proliferation characteristics of traditional MSRs and the MCFR.

Characteristic	Thermal molten salt reactors	Molten chloride fast reactor
Fissile material	^{233}U , ^{235}U and/or ^{239}Pu	^{235}U and/or ^{239}Pu
Operating mode	Neutron moderated, thermal spectrum	Unmoderated, fast spectrum
Fission product poisoning	Significant	Limited
Online processing	Yes, including fissile separations	Limited, no fissile separations
Ongoing fissile feed	Yes	No, system is fed depleted or natural uranium after start-up
Supports eventual elimination of enrichment	Not in U-Pu cycle	Yes
Material attractiveness	Varies	Reduced due to presence of lanthanides, which are chemically similar to Pu

fuel salt acts as a coolant and must be pumped to the external heat exchanger. This layout increases fissile fuel inventory and results in delayed neutron loss in the primary circuit. The advantage of internal cooling is that the salt does not need to be extensively pumped out of the core. The presence of coolant and separating structural materials in the core, however, deteriorate the neutron economy. Many of these concepts rely on metallic tubes with very thin walls, profiting from the low pressure difference, or on SiC tubes, because of its low parasitic capture.

The very hard neutron spectrum and the related excellent neutron economy of MCFR enables strong breeding in the U-Pu cycle or even the operation in breed-and-burn cycle. In this case, discharged fuel will be replaced exclusively by fertile feed, typically depleted or natural uranium, reducing or eliminating the need for continued enrichment. For concepts with a single fuel salt, or actually single fissile zone, the discharged fuel represents an average fuel composition. It can be used, once a sufficient amount is collected, to start another breed-and-burn reactor. This option can substantially postpone the final decision about recycling or disposal of the spent fuel. Breed-and-burn MCFR might achieve a very high uranium utilization of $\sim 35\%$. This is ~ 60 times the utilization of natural uranium in contemporary light water reactors; both operating in a once-through fuel cycle.

MCFR concepts have been developed since the 1950s and continue to draw interest due to key technology differences and advantages relative to solid fueled reactors. However, many of the key technologies are at low technical readiness and require further research and development. Specific areas of focused research and development include molten salt synthesis, chemistry and corrosion, accommodation of the irradiation damage to the core vessel, source term development, irradiation testing, reactor licensing, nuclear safeguards and nonproliferation, instrumentation and controls, and component vendor development. Applied research in the areas of molten salt chemistry and source term quantification are required. Additional structural material development and irradiation testing to support operational and economic requirements are also underway. Lastly, remote handling technologies in support of continuous operations remain an area for future development.

Active development in these areas along with further reactor design and modeling is underway by numerous international partners across industry, government, and academic research labs. Government agencies, the International Atomic Energy Agency, non-governmental organizations, and other research agencies maintain active forums and working groups with industry vendors to facilitate the advancement of MSRs. Although much work remains in specific areas, the promise of MCFR technology remains a strong driver to advance to the technology to support worldwide deployment.

Glossary

ATR advanced test reactor.

BDBA beyond design basis accident.

BOEC/EOEC beginning/end of equilibrium cycle.

BOL/EOL beginning/end of life.

Breeding Converting a fertile isotope into a fissile one by capturing a neutron. Usually the fertile isotope ^{238}U to the fissile isotope ^{239}Pu . Also the fertile isotope ^{232}Th (natural thorium) to the fissile isotope ^{233}U .

Burnup A measure of the amount of fission energy released from a given quantity of fuel. One unit used for such a measure is FIMA = Fraction (usually given in %) of Initial Heavy Metal Atoms that has fissioned. A more wide-spread unit is MWd kg^{-1} ($= \text{GWd ton}^{-1}$) that measures the amount of thermal energy released from unit weight of the initially loaded HM.

Cladding The structural material that separates the nuclear fuel from the coolant. In fast reactors it is usually made of steel. In light water reactors it is usually made of an alloy of zirconium.

DBA design basis accidents.

EPZ emergency planning zone.

FCCI fuel-cladding chemical interaction.

FFTF fast flux test facility.

IES integrated energy system.

INL Idaho National Laboratory.

IVS in-vessel storage.

LCOE levelized cost of electricity.

LWR light water reactor.

Neutron flux Number of neutrons crossing a unit area per second. Reaction rates, such as the fission rate, are proportional to the neutron flux.

PIE post-irradiation examination.

PPS plant protection system.

SFR sodium-cooled fast reactor (Heidet, 2021).

STC Sodium temperature coefficient; the effect on the effective multiplication factor (k_{eff} ; the ratio between neutron production rate and neutron loss rate) due to a change in the sodium temperature.

Subcritical/critical core A core that cannot/can sustain a fission chain-reaction.

TREAT transient reactor test facility.

TRL technology readiness levels.

TWR[®] traveling wave reactor.

UTOP unprotected transient over power.

TWR definition and key advantages of TWR technology

The traveling wave reactor is a fast spectrum reactor that operates in a once-through fuel cycle and uses conversion of fertile material into fissile material and subsequently burns bred-in fissile material in situ, thus enabling substantial reduction of the need for enrichment and higher utilization of uranium resources. It is a breed-and-burn reactor whose operation includes the periodic loading and discharge of fuel capable of sustaining an equilibrium state of critical operation with fuel reloads that without in situ breeding would render that specific fast spectrum core subcritical. Thus, the reload fuel, which if fully loaded into the core would render the core subcritical, is bred in the core through neutron captures on fertile fuel isotopes and converted into fissile isotopes that are then fissioned (burned) in situ, maintain criticality and produce power. More detailed discussion on breed-and-burn fast reactors and their background is discussed in [Qvist \(2021\)](#) and [Hejzlar et al. \(2013\)](#). The concept operates on the basis of so called breed-burn waves and their relative movements versus fuel, where either the fuel or the waves may move relative to stationary observer. The concept with stationary fuel and moving breed-burn waves is described in CANDLES concept by [Sekimoto \(2021\)](#). The version with the stationary wave that keeps nuclear reactions fixed in one place and moves the fuel into the wave was selected by TerraPower, LLC (TerraPower®) as the most practical embodiment for development and will be described in this Chapter.

The selection of TWR concept and origins of TerraPower, LLC have their beginnings in the 2006 deliberations between Bill Gates, Nathan Myhrvold and Lowell Wood on how to provide sustainable, scalable low carbon energy for the world. A large number of reactor types, both existing and new, were considered with respect to improvements in areas of safety, waste, efficiency, economics, weapons-proliferation resistance and terrorist-risk reduction. During these assessments, the TWR concept, advocated at that time by Lowell Wood, was identified as offering improvements in all these areas. Many possible fuel and coolant options were considered and explored in order to evaluate which option was the most promising and practical embodiment. Sodium cooled Fast Reactor (SFR) using metal uranium fuel was identified as the most promising TWR concept. This is because sodium coolant offers excellent cooling capabilities enabling high power densities and metal fuel has high uranium density and hard neutron spectrum that is important for effective breed-and-burn wave process. In addition, sodium coolant technology is the most mature among other fast reactor coolant candidates due to appreciable operating experience in experimental, prototype, demonstration, and commercial SFR units worldwide and is compatible with early deployment time scales.

TWR cores are distinguished from other fast reactors in that they can operate in equilibrium with subcritical reload fuels, i.e., fuels that if fully loading these cores would make the fast neutron spectrum cores subcritical. These fuels include medium assay low enriched uranium (enrichment less than 10%), low enriched uranium (less than 5%), natural uranium, depleted uranium or spent fuel from light water reactors (LWRs). The ultimate TWR concept with most benefits is realized when TWR core operates with fuel reloads from depleted uranium. This means that after reactor startup period, the only fuel that is required is depleted uranium and there is no need for enrichment and reprocessing facilities to sustain operation of the first reactor and its successors. As a result, fuel cycle is significantly simplified compared to the current LWR fuel cycle, as shown in [Fig. 1](#).

Such simplification of fuel cycle has a number of benefits:

Fig. 1 Simplified TWR fuel cycle versus LWR fuel cycle. Black crosses indicate eliminated step of LWR cycle or reduction of waste, such as less spent fuel storage and less waste to repository. TWR fuel cycle minimizes the need for mined natural uranium, enrichment services, temporary fuel storage, fuel reprocessing and final waste disposal.

- Significantly reduced mining of natural uranium resources. TWR reactors operating on depleted or natural uranium use up to 30 times less natural uranium than LWRs. The reasons for such a large improvement include the elimination of enrichment for fuel reloads and much more energy extracted from TWR fuel assemblies than in LWRs.
- Substantially reduced number of spent fuel assemblies and waste volume; by about 80% less than for LWRs per unit energy generated. This is primarily due to significantly larger energy extraction per unit fuel mass due to high burnups of TWR fuel and also because of higher TWR fuel loading per unit volume and higher plant efficiency than for LWR. Consequently, the requirements for temporary spent fuel storage and for waste repository are correspondingly reduced. Furthermore, using depleted uranium rather than enriched uranium, TWR plants consume existing tailings from the enrichment process that would otherwise add to waste obligations.
- Large reduction of enrichment services. Only the first core requires enriched fuel, all reloads and successor plants¹ do not require enriched fuel reloads.
- No need for reprocessing. TWR plants avoid the cost of building and operating reprocessing plants as well as the related waste cleanup costs, while still supporting large increase of utilization of natural uranium compatible with worldwide scale deployment (Petroski and Wood, 2012).
- High proliferation resistance. By eliminating the need for reprocessing and reducing enrichment needs, TWR technology bypasses two main proliferation concerns. Very high burnup of TWR fuel renders plutonium isotopic composition of spent TWR fuel unattractive for proliferators. In addition, long TWR fuel residence time and infrequent refueling operations—about once in 10 years, restrict access ability to fuel.
- Lower fuel cycle cost. Simplified fuel cycle reduces the cost of fuel cycle due to reduced enrichment and reduced volume of spent fuel and associated repository and waste management costs.

In addition to the benefits from TWR fuel cycle, TWR plant also exhibits safety benefits of pool-type SFRs with metal fuel. These include:

- Elimination of loss of coolant accident due to low pressure sodium coolant, no large pipes with primary coolant outside the reactor vessel, and the use of a guard vessel surrounding the reactor vessel with no penetrations below the coolant surface level.
- Long times available before fuel and coolant temperatures reach their limits due to large thermal inertia of the sodium pool in the vessel.
- No need for electricity supply to drive emergency cooling systems due to passive decay heat removal systems that remove decay heat to air by natural circulation indefinitely.
- Inherent reactor transition to a safe state in beyond design basis accidents with failure to shut down. This is because in case that control rods and even standby shutdown rods fail to drop into the core to stop the fission reaction, reactivity coefficients of metal fueled TWR core result in such reactor response that significant damage to fuel is prevented.
- Compatibility of metal fuel with sodium coolant that eliminates fuel/coolant reaction and progression of fuel damage even in case of cladding breach. In addition, dispersal characteristics of metal fuel in severe accidents lead to reactivity reduction even in case of fuel melting.
- Iodine and cesium fission products that drive dose rates stay within metal fuel and the sodium pool, so their release in severe accidents is thus very limited (Grabaskas et al., 2016). This feature of the TWR reactor together with other safety benefits listed above result in a much lower source term and radiological risk and thus in a greatly reduced emergency planning zone (EPZ). TWR plants are expected to be able to achieve having a small EPZ, possibly within the plant site boundary. Eliminating the need for evacuations beyond plant site reduces cost of emergency planning and allows more flexible plant siting.

Overall, TWR technology can lead to a sustainable, scalable reactor infrastructure that in its ultimate mode of operation requires only depleted or natural uranium, tremendously enhances energy security, reduces fuel costs, and exhibits good proliferation resistance without need for reprocessing facilities. The very significant benefits offered by the TWR system provide strong incentives for the expeditious development and deployment of the TWR technology.

Key challenges for TWR technology development and mitigation strategies

The concept of breed-and-burn reactors is not new, first being proposed in the late 1950s by Feinberg (1958). The review of various studies of breed-and-burn reactors since that time is provided by Qvist (2021). However, these early studies focused primarily on neutronic analyses of the wave propagation without looking closely at other aspects of the reactor design, such as fuel performance, thermal hydraulic and mechanical design limitations. Considering all engineering and fuel design limits in a systematic manner to develop practical embodiment of a functional reactor brings challenges that need to be overcome before TWR plants can be successfully demonstrated and deployed. This section will discuss key challenges of the TWR core design and solutions including innovative approaches developed by TerraPower, LLC, to resolve these challenges.

Any reactor design has to meet many limits, but for the purpose of this discussion, we will focus only on the key limits impacting the feasibility of a breed-and-burn reactor. Fig. 2 shows these limits and main design levers that can be used to affect these limits.

¹Successor TWR plant is a new TWR unit that uses as its initial core the fuel discharged at end of life from its predecessor plant.

Fig. 2 Key TWR core design limits and design levers to impact the limits. Green fields indicate desirable regions for key design parameters that need to be kept within design limits designated by thick red lines. Impact of design levers on the limits is depicted by dashed lines where green color indicates benefit, i.e., increasing the desirable green field and red color indicates negative benefit. For example, softening the neutron spectrum reduces sodium temperature coefficient (STC), but increases minimum peak burnup limit.

High minimum peak fuel burnup

Fuel burnup, which is a key parameter for fuel performance, needs to lie in the green field above the minimum peak burnup and below the thermo-mechanical peak burnup limit, which is determined by cladding strain from irradiation or thermal creep. The former limit is unique to breed-and-burn reactors as the reload uranium assemblies with very low fissile content need to first breed enough fissile material to sustain the chain reaction, which requires certain minimum burnup. The lower the enrichment of reload fuel, the higher the minimum peak burnup limit. For the most attractive TWR embodiment running on depleted uranium, minimum peak burnup limit is about 30%.² The peak allowable burnup limit can be increased by increasing cladding thickness. However, larger cladding thickness results in larger neutron parasitic losses and leads to a higher required minimum burnup. Typically, the required minimum burnup is more sensitive than the peak burnup limit is to variations in cladding thickness, and hence a reduced design window may result from increasing thickness. A more effective design lever to increase the peak burnup limit is reduced smear density.³ Less fuel per pin provides more space for swelling caused by fission products accumulation reducing cladding stress. However, less fuel leads to higher minimum required burnup. Moreover, for metal fuel with sodium bond⁴ more sodium in the pin yields a more positive sodium temperature coefficient (STC).

To meet the requirement of high minimum burnup while still meeting fuel performance limits, TerraPower, LLC is developing fuel pins⁵ with smaller smear density than the ~75% used in traditional SFR metal pins. In addition, other design levers shown in Fig. 2 that tend to increase minimum fuel burnup are optimized to keep the peak minimum burnup as small as possible. The ultimate TWR plant that can operate with depleted or natural uranium fuel will require venting gaseous fission products from the fuel pins to reduce pressure buildup and thus reduce stresses and cladding strain. This is accomplished through a pin vent allowing venting of gases in a controlled manner into sodium coolant and with features minimizing escape of cesium. The impact on plant design is a small amount of Cs137 released into the sodium coolant, which is removed with reticulated vitreous carbon traps, and an increased amount of fission gas that requires higher capacity of the cover gas processing system and storage of Kr85 in shielded vessels. Due to this continuous online removal of Cs137, the end result is a primary coolant activity similar to that of current LWRs.

Another consequence of high burnups necessary to achieve breed-and-burn operating mode on depleted uranium is a high neutron dose on cladding material. The highest dose that has been reached up to date in metal fueled test pins with ferritic martensitic steel cladding is ~200 dpa⁶ (Toloczko et al., 1994), while the TWR cladding requires doses of up to ~500 dpa. The higher dose increases cladding strain from void swelling and irradiation creep. The above strategies for addressing high peak burnup (using low smear density and fuel pin venting) also mitigate the consequences of high dose on irradiation creep-driven cladding strain since they eliminate the stress from internal gas pressure and reduce the creep strain from fuel cladding mechanical interaction. Fig. 3 shows an example of how pin venting can significantly increase burnup capability under total cladding strain limit in comparison with sealed pin.

²That is, at least 30% of the fed uranium fuel needs to be fissioned.

³The smear density is the fraction of the maximum nominal fuel density.

⁴The sodium bond is sodium that is inserted into the as-fabricated fuel rod to fill the initial radial gap between the fuel and the cladding for better heat transfer.

⁵Also referred to as “fuel rods.”

⁶Displacements per atom; a measure of the radiation damage induced by, primarily, energetic neutrons bombardment.

Fig. 3 Comparison of cladding strain for sealed and vented pins for irradiation history in TWR core. For the same cladding strain limit, achievable peak burnup can be significantly increased.

Fig. 4 Demonstration of irradiation performance improvement of TerraPower optimized HT9 (TP HT9) using ion irradiation with direct comparison against FFTF HT9 cladding. Black dots are data from neutron irradiation in FFTF reactor. Blue dots show ion irradiation of archived HT9 material from FFTF and squares and diamonds shows ion irradiation data for Heats 3 and 4 for optimized TP HT9.

To further reduce cladding strain and duct dilation,⁷ TerraPower, LLC is developing an advanced ferritic-martensitic steel HT9 with an optimized microstructure that is expected to exhibit very low void swelling rates and irradiation creep up to ~ 500 dpa. Fig. 4 shows that in direct comparison with archived HT9 used for FFTF (Fast Flux Test Facility) reactor, TerraPower optimized HT9 steel has substantially lower swelling.

⁷Duct dilation is bulging of hexagon duct walls in radial direction towards adjacent duct walls.

Duct dilation

Fuel pins are surrounded by ducts that direct the sodium flow through assemblies and are exposed to stresses from pressure differential⁸ and to irradiation creep causing the ducts to dilate with time. Similarly as for cladding, TWR ducts are exposed to high dose⁹ of high energy neutrons increasing void swelling and irradiation creep. As the duct dilates it closes the gap available between the ducts of adjacent assemblies. It is desirable that at the end of assembly life, the duct walls of adjacent ducts do not come into contact to avoid excessive withdrawal and insertion forces that would impair fuel shuffling. Duct dilation can be reduced by increasing the duct wall thickness. This design approach adds steel in the core and increases minimum fuel burnup, reducing the design window for fuel pins. Traditional fast reactors use thicker ducts and boost enrichment to overcome the penalty of parasitic losses, but this approach is not possible for the TWR cores where depleted uranium is feed.

To keep the duct dilation within prescribed limits innovative duct design that exhibits smaller dilation has been developed. The geometric features of the duct design and the optimized HT9 material with low swelling performance shown in Fig. 4 are key aspects of the design enabling smaller dilation.

Sodium temperature coefficient

The third important limit comes from the sodium temperature coefficient. This coefficient is typically positive for large SFR cores.¹⁰ However, its value needs to be kept small enough so that it can be balanced by other reactivity feedbacks¹¹ that are negative, such as Doppler coefficient, core radial expansion/bowing coefficient, fuel axial expansion coefficient and control rod driveline expansion coefficient, to yield overall net negative reactivity feedback. This is typically achieved in sodium cooled reactors by a large enough increase in the neutron leakage probability. This contradicts low leakage needed for TWR core to support breed-and-burn operation at reasonable minimum burnups. Another approach is the use of softer spectrum through introduction of moderators, but this leads to more parasitic absorptions and increased minimum burnup, reducing the burnup design space as indicated on Fig. 2. Therefore, minimizing the sodium fraction in the assembly is the main design lever remaining to keep the sodium temperature coefficient within acceptable bounds. This is accomplished through the following means:

1. the use of a tight pitch hexagonal lattice to keep the amount of coolant between the fuel pins as small as possible while keeping an acceptable pressure drop,
2. the minimization of the gap between the fuel assembly ducts while providing enough space for duct dilation and swelling to maintain acceptable assembly withdrawal forces, and
3. the design of a fuel pin without a sodium bond, replacing it with mechanical bond, as discussed below.

In addition, TerraPower, LLC is developing special passive reactivity devices that upon coolant temperature increase reduce reactivity by passive means to counterbalance positive reactivity insertion from sodium temperature feedback.

Feasibility of TWR core operating on depleted uranium

This section provides the physical description and layout of an example (not necessarily optimized) TWR core and its key performance parameters to assess if the operation on depleted or natural uranium in equilibrium is feasible using the design approaches outlined above. The example is shown for commercial units sized for 1200 MWe power rating.

Fig. 5 shows an example TWR core map with illustration of fuel shuffling scheme. The core initially contains a total of 864 fuel assemblies with 510 enriched fuel assemblies and 354 depleted uranium fuel assemblies. The core effective radius is 3.25 m and the active core height is 2 m. The TWR fuel assemblies have innovative features enabling achievement of high burn-up and dpa capabilities consistent with the requirements of TWR breed-and-burn operation on depleted uranium described in the above section. These assemblies have 217 wire wrapped fuel pins arranged in a tight triangular lattice surrounded by advanced ducts that can withstand neutron induced radiation damage up to ~500 dpa. The pins have a significantly lower effective smear density in the range of 50% to 60% versus 75% for typical SFR metallic fuel pins and are vented. The ducts, as well as pin cladding will be fabricated from optimized ferritic martensitic steel with high resistance to swelling to accommodate high neutron fluence, but other components of the assembly (e.g., end fittings and nozzles) will use stainless 316H. Key fuel assembly dimensions are listed in Table 1.

The key feature of the TWR core is its ability to sustain critical operation indefinitely while being refueled with depleted or natural uranium. To demonstrate this feature, the reactor must be able to operate in an equilibrium cycle using only depleted or natural uranium as feed fuel. In an indefinitely sustainable equilibrium cycle, the reactor is critical over the entire cycle, and it is possible to restore the Beginning of Equilibrium Cycle (BOEC) state from the End Of Equilibrium Cycle (EOEC) state by shuffling the fuel

⁸Between the coolant pressure inside the fuel assembly and the sodium filling the gap between the fuel assemblies.

⁹Also referred to as fluence = time integrated flux.

¹⁰A reduction in the sodium density results in a hardening of the core neutron spectrum that causes a positive reactivity feedback and an increase in the leakage probability of neutrons out from the core that has a negative reactivity feedback.

¹¹A reactivity feedback coefficient is the change in the core effective multiplication factor (See definition in Glossary) due to a one degree change in either the coolant (affecting core radial expansion and control rods driveline expansion) or the fuel (affecting Doppler effect and fuel axial expansion).

Fig. 5 Example of TWR core map with illustration of fuel management using convergent-divergent shuffling. Dark red colored C assemblies denote center driver fuel, assemblies designated by letter I designate inner driver fuel, M and O assemblies indicate middle and outer driver fuel, respectively, F assemblies are depleted uranium feeds, blue colored B assemblies designate reflectors, P are control rods and S are standby shutdown rods. The arrows indicate how the shuffling of assemblies is performed during shutdown.

Table 1 Key fuel assembly dimensions for example TWR core.

Parameter	Value (mm)
Clad outer diameter	10.2
Clad thickness	0.40
Assembly outer flat-to-flat	174.0
Duct thickness	4.00
Wire diameter	0.86

assemblies. Shuffling the fuel assemblies involves discharging the most highly burned fuel from the core, repositioning the assemblies left in the core, and introducing new fuel assemblies consisting of fresh fertile fuel (depleted or natural uranium).

Analyzing the equilibrium cycle state is important because it sets the minimum requirements on fuel burn-up and dpa needed for burning depleted uranium. Burn-up and dpa levels affect the distortion and swelling of both the fuel pins and assembly ducts and therefore need to be accommodated in the design. Because the equilibrium cycle consists of a large amount of bred plutonium and fission products, it is also the most challenging from the perspective of reactivity coefficients and transient response.

Equally important to the equilibrium cycle is the transition from a fresh enriched startup core to equilibrium state. This must be done in such a manner that the power produced in each assembly location remains nearly constant to avoid power-to-flow discrepancies at any point during the transition period. The primary challenge of designing the transition fuel management is minimizing the amount of enriched material required to reach equilibrium while maintaining a constant radial power distribution.

The initial fresh core layout is shown in Fig. 5. The uranium in the enriched assemblies vary between 5.5% and 13% U-235. The initial core layout, cycle length, and enrichment distributions were determined by iteratively matching the target equilibrium cycle power distribution, which in turn was determined as the optimal result of a systematic optimization sweep over a variety of fuel management options.

TWR Reactor's fuel management scheme using a convergent-divergent path through the core is shown on Fig. 5. The cycle length is 550 EFPDs. There is a feed stream of 30 natural uranium assemblies per cycle. Feed assemblies enter the core at the periphery, as indicated on the figure, and are gradually shuffled inward as fissile fuel is bred. Then they are moved to the center of the core and start moving away from the center until they reach the burn-up limit, when they are discharged from the core at around ring 15. The

discharged assemblies are stored in the In-Vessel Storage (IVS) for 5 cycles, hence the fresh feed fuel delivery into the reactor vessel and removal of burned assemblies from the vessel happen once every 10 years.

The primary parameters of interest are the peak burnup (for the fuel performance limits), k -effective (for neutronic constraints), the structural dose (for cladding and duct performance), and the power density profile (for cooling constraints).

The k -effective evolution of the TWR core over several selected equilibrium cycles is shown in Fig. 6. It remains between 1.006 and 1.021, with a typical burn-up reactivity swing¹² of 2% dk/k. The larger k_{eff} than 1.0 is used to provide margin to account for uncertainties. In an actual reactor, k_{eff} will be maintained at 1.0 all the time using control rods. During every cycle, the k_{eff} increases because the TWR core is breeding new plutonium. The saw-tooth drops of reactivity are associated with each shuffle operation, which are designed to bring k_{eff} down through addition of depleted uranium feed assemblies that behave as neutron absorbers.

Neutronic parameters and reactivity coefficients vary significantly between the Beginning of Life (BOL) and EOEC due to transition of primarily fissioning isotopes of ^{235}U at BOL to ^{239}Pu at EOEC with effective delayed neutron fraction changing from 0.0068 at BOL to 0.0035 at EOEC. Doppler coefficient is negative and relatively small, consistent with metal fuel cores, undergoing BOL to EOEC change from $-0.051 \text{ } ^\circ\text{K}^{-1}$ to $-0.092 \text{ } ^\circ\text{K}^{-1}$. Fuel axial expansion coefficient is also negative changing from $-0.04 \text{ } ^\circ\text{K}^{-1}$ to $-0.08 \text{ } ^\circ\text{K}^{-1}$ and negative radial expansion coefficient increases from $-0.062 \text{ } ^\circ\text{K}^{-1}$ to $-0.15 \text{ } ^\circ\text{K}^{-1}$ between BOL and EOEC. Sodium temperature coefficient is positive with small value of $0.032 \text{ } ^\circ\text{K}^{-1}$ at BOL increasing to $0.27 \text{ } ^\circ\text{K}^{-1}$ at EOEC, without considering the effect of engineered passive reactivity devices. Even with EOEC positive sodium temperature coefficient, the net temperature and power reactivity coefficients are negative.

Keeping the power shape relatively constant throughout each cycle and during the transition to equilibrium is required to match power to flow in each fuel assembly at all times. The BOL and EOEC radial power distributions are shown in Fig. 7. The low-burnup assemblies that jump into the center of the core are less reactive than the higher-burnup assemblies in the central rings, leading to an annular power distribution. There is very little power in the outer region of the core where the depleted uranium captures most of the neutrons leaking from the power-producing regions of the core while generating very little fissions.

The flow to each assembly is delivered through receptacles located in a high pressure plenum between a lower and upper grid plates. To maintain appropriate power to flow ratio at all times, each receptacle employs orifice plates designed to deliver appropriate flow rates. There are 20 orifice zones to distribute flow rates for matching power to flow in each region to maintain peak clad temperature below $625 \text{ } ^\circ\text{C}$ (a steady state operating temperature limit that accounts for uncertainties). Maximum bundle pressure drop is 0.5 MPa and the core provides $500 \text{ } ^\circ\text{C}$ core average outlet temperature.

Table 2 summarizes key TWR core parameters of interest. The peak burnup of 28% and peak cladding radiation damage of 520 dpa is achieved after residence time of 46 years. The ALCHEMY fuel performance code (Latta et al., 2012; Touran et al., 2017), developed in house, was used to evaluate TWR fuel pin compliance with the engineering design basis limits. Fuel performance results show that peak cladding strains could meet the 3% design basis limit. The thermal creep component which may cause creep rupture was well below the 1% limit. The models used to predict fuel performance need to be confirmed through an irradiation program.

The fuel duct assembly dilation is required to be less than the envelope created by the surrounding fuel assemblies. For the TWR reactor core assembly design, allowable dilation is equal to 3.5 mm at refueling conditions.

The unrestrained dilation of the TWR fuel assembly was calculated using the commercial finite element analysis tool ABAQUS 6.11.1 (ABAQUS, 2011) with custom creep and swelling materials subroutines incorporating irradiation and thermal creep and swelling correlations for optimized HT9 material. The important loadings on the assembly include the dpa rate, the differential pressure across the duct wall, and the duct material temperature histories over life of the duct. These loads are spatially dependent (i.e., vary as a function of assembly height from the bottom of the duct) and time dependent (i.e., vary as the assembly is shuffled in the

Fig. 6 k -Effective evolution over several equilibrium cycles.

¹²Change in reactivity over the cycle.

¹³¢ - cent is 1/100 of a dollar (\$), which is a unit of reactivity normalized to delayed neutron fraction (i.e. neutrons coming with delay from fission products versus prompt neutrons coming directly from fissions) useful in determining the response of reactor to insertion of reactivity.

Fig. 7 Example of Power distribution at BOL (Left) and EOEC (right). Dark red indicates highest power, dark blue indicates lowest power.

Table 2 Key parameters of interest for TWR core analysis.

<i>Parameter</i>	<i>Value</i>
Peak burnup (%FIMA)	28
Peak cladding dose (dpa)	520
Core pressure drop (MPa)	0.45
Cycle length (EFPD ^a)	550

^aEffective full power days.

core). The duct performance analysis confirmed that for the load case and geometry resulting in the greatest amount of duct dilation, the duct would remain within the allowable envelope when lifted from or inserted into the core.

Safety analyses were performed using SAS4A-SASSYS1 code (Cahalan and Fanning, 2012). A number of Design Basis Accidents (DBA) have been analyzed and confirmed to meet all the limits with margin. Only one representative DBA, which is one of the most challenging DBAs, protected loss of flow, is presented as an example on Fig. 8. This transient is initiated by partial loss of primary coolant flow due to pump failure. With the loss of flow, the Plant Protection System (PPS) shuts down the reactor either due to higher temperature, low flow or high power to flow ratio. Before the shutdown occurs, peak cladding temperature is increasing due to power-to-flow imbalance. After the shutdown signal is transmitted to control rods, control rods drop inserting negative reactivity. Peak cladding temperatures never exceed the 650 °C design limit for DBAs.

The TWR technology's goal is to achieve higher safety protection for Beyond Design Basis Accidents (BDBA), such as in unprotected events, where the reactor fails to shut down. An example of such a scenario is an Unprotected Transient Over Power (UTOP) accident initiated by a severe positive reactivity addition. All PPS systems are assumed not to function. For this BDBA class of accidents it is desirable that the reactor response achieves stable conditions without any sodium boiling in the core. An example of TWR response to reactivity insertion of 0.14\$ from partial rod withdrawal (limited by rod stops) is shown in Fig. 9. The reactor power peaks at 2.3 times the nominal power and stabilizes back at original power level due to net negative coefficient of reactivity. The maximum peak cladding temperature reaches about 900 °C and coolant temperature remains below sodium boiling. The best-estimate results confirm that TWR core is nominally stable without any additional passive reactivity device. Passive reactivity devices will reduce peak temperatures and they are needed for unprotected loss of flow.

Areas of application

Traditional application of plants based on TWR technology is electricity generation. However, because this is a sodium-cooled reactor with outlet temperatures in the range 500 °C–540 °C, e.g., significantly higher than those of < 300 °C from LWRs, its applicability goes well beyond electricity generation. To address the need for innovative technology solutions for clean energy generation (Moniz et al., 2019), TerraPower, LLC is developing a technical architecture that combines nuclear power and thermal storage to reduce cost, broaden application and increase the value stream. This architecture can provide maximum flexibility for nuclear applications and sizing (e.g., energy capacity; electric, thermal, or both) as both energy generation and distribution transition to their

Fig. 8 Example of TWR plant response to protected loss of flow.

Fig. 9 Example of TWR plant response to protected loss of flow.

future form (which is naturally uncertain). An example illustration of this new architecture, designated TWR Integrated Energy System (IES) referred to as TWR-IES is shown in Fig. 10. In this architecture, the nuclear reactor is used as a source of heat that is sent to a separate thermal energy storage system which is located outside of the nuclear site boundary. This integrated energy system architecture potentially brings four main beneficial features:

Fig. 10 Integrated energy system—synergy between thermal energy storage and TWR technology increases nuclear versatility. Storage (blue and brown large tanks) allows decoupling of reactor from power conversion applications (illustrated in the right bottom corner as modular supercritical CO₂ cycle) and enables rapid load following for electricity generation and use of industrial heat off-site (large buildings on the right illustrating heat consumers). Commercially available solar salt can be used as heat transport and storage fluid.

- (1) reduces total system cost,
- (2) enables flexible electric demand (load) following and “profit following” in grids with larger penetration of renewables,
- (3) provides high temperature process heat at competitive cost with natural gas, not possible with LWRs, and
- (4) supports hydrogen generation through high temperature electrolysis.

These capabilities make carbon reduction possible in industrial processes and the transportation sector that account for about 75% of the world’s greenhouse gas emissions.

The cost of nuclear power plants is the main challenge facing nuclear power in many Western markets. Recent studies have shown that the main cost driver is not the nuclear technology itself, but rather the cost of large scale construction projects regulated by strict nuclear standards (Dawson and Sabharwall, 2017) and that the greatest promise for capital cost reduction is not necessarily in the technology advances of a reactor itself but in the overall plant design (Buongiorno et al., 2018). By greatly simplifying and reducing the scope/complexity of the construction project within the nuclear site, TWR-IES directly addresses what experts have concluded to be the main cost drivers. For example, in the TWR-IES architecture the nuclear plant and the scope of the nuclear construction project is reduced to its most basic form. The simplified reactor becomes a producer of heat energy. The interface between the reactor and the rest of the system is a heat exchanger. The remaining system components are functionally and spatially separated from the reactor outside of the nuclear site beyond the heat exchanger. In this architecture, the thermal energy storage, and balance of plant with power conversion systems are now constructed and operated in a less regulated, less expensive, and fully commoditized environment. Molten salt thermal storage systems are relatively inexpensive, an order of magnitude less than battery storage, and have recently achieved commercial readiness on GWh scale, such as 4.2GWh Solana Generating Station in Arizona (Peltier, 2014), in support of the concentrated solar power industry. Also, very small EPZ due to excellent safety benefits (see section “TWR definition and key advantages of TWR technology”) enables closer siting of these reactors to the nuclear process heat consumers than is possible for current LWRs.

The proposed TWR-IES system also addresses another challenge facing nuclear power in current and future electricity markets with increasing variability of electricity production, as discussed in Forsberg (2018). As the fraction of power generated by intermittent renewable sources is increasing, there is large variation in electricity supply with overproduction during typically the 9 a.m.–4 p.m. time window with solar energy pushing electricity prices down to very low values or even negative territory. Current nuclear plants have typically limited flexibility of rapid load following and they also need to keep high capacity factor to achieve low Levelized Cost of Electricity (LCOE). So even if they could match daily varying power demand, their LCOE is increased as capacity factor is decreased, making it harder for them to compete. Salt thermal storage allows TWR plant operation at 100% capacity factor and store energy in salt tanks and sell electricity during periods when demand is high and price is also high. Initial studies, using actual market data and a hypothetical flexible generation nuclear plus storage system, have shown that appreciable increases in revenue can be obtained by accessing these higher value prices.

As discussed in MIT (Buongiorno et al., 2018) and Breakthrough Energy (Moniz et al., 2019) reports, expansion of decarbonization into other industrial processes is an important challenge to be addressed. Energy consumption primarily in the form of heat in this sector is enormous with petroleum and chemicals being major consumers. TWR-IES with its high outlet temperatures of ~510 °C–540 °C and molten solar salt compatible with these temperatures provides opportunity to supply heat to large number of consumers up to temperature of 500 °C, such as petroleum refineries, various chemical plants, soda ash production plants, pulp and paper production plants, food processing plants and others.

The transportation sector is responsible for the second largest share of global energy consumption after industrial manufacturing. Until recently, transportation has been solely driven by gasoline fuels with no participation of clean nuclear energy in this sector. This is changing with recent arrival of electric cars driven by batteries and fuel cells running on hydrogen. TWR-IES can

provide both electricity and hydrogen products carbon-free and have significant impact on decarbonization of the transportation sector.

The TWR-IES can generate hydrogen using high temperature electrolysis and heat. It uses the heat from the heat storage to generate steam from water and electricity to raise temperature in the electrolyzer to 750 °C–900 °C through ohmic heating and thermal recuperation from effluent streams. The heat exchangers in the electrolyzer recuperate the heat from hydrogen and oxygen streams so only a small amount of ohmic heating is needed to keep the electrolyzer at desired temperature. Efficiency of this process is high as documented for a similar application by [Yildiz and Kazimi \(2004\)](#). TWR-IES can generate both electricity to charge car batteries and hydrogen at the same time. When electricity is not needed, it can generate more hydrogen and store hydrogen for distribution throughout the country as is done with gasoline. Unlike GW-scale thermal storage, which is limited to hours-long duration and relatively short distances for transport, hydrogen can be stored for much longer times and can be transported over long distances. The main challenge today remains in reduction of cost of electrolysis equipment and cost of hydrogen transportation to be competitive with gasoline.

Because climate change is a worldwide problem, any nuclear reactor providing carbon free heat, electricity and clean energy carrier, such as hydrogen, needs to be deployable on a worldwide scale, exhibit good uranium utilization and be proliferation resistant. TWR Reactors operating on depleted or natural uranium in a once through cycle is the perfect candidate as it has all these features. For more detailed discussion on non-electric applications of nuclear power reactors, readers are referred to Section 8 of this encyclopedia, specifically chapters by [Forsberg \(2021\)](#), [Bienvenu \(2021\)](#), [O'brien \(2021\)](#), as well as other chapters.

Development status and overall TWR program

Confirmation of the feasibility of the core operating on depleted uranium fuel reloads, described in section “Feasibility of TWR core operating on depleted uranium” is only the first small step before the actual TWR plants can be deployed. The key areas of development include qualification of new mechanically bonded fuel with FCCI barrier,¹⁴ cladding and duct performance up to doses of 500 dpa, development and validation of analysis tools and many other aspects of the design.

The fuel and core components represent a significant leap in performance beyond existing experience. Satisfactory material and fuel performance at high burn-up and dpa level are essential to the TWR Program. TerraPower, LLC has a significant ongoing fuels and material development program to develop and qualify fuel and materials for TWR core components. The program addresses key technology challenges and involves the following key activities:

- Legacy data collection. Data from sodium bonded fuel pins from EBR-II and FFTF reactors are analyzed to expand the database for benchmarking the models against irradiated data and better understanding of key phenomena for modeling behavior of metallic fuel. Database of fuel pin as built characteristics, irradiation history and Post-Irradiation Examinations (PIE) has been developed. FFTF metal fuel pins are of special value since their size and histories are much closer to commercial fuel form than EBR-II pins.
- Development of commercial scale fuel material production. Extrusion was selected as a commercially scalable metal fuel fabrication for TWR fuel because it is a mature industrial process with high throughput and capable of delivering dimensionally precise products without major waste stream associated with historic casting process. First U-10Zr¹⁵ extruded fuel was made in December 2016 at lab-scale fuel fabrication facility at INL, and enriched U-10Zr fuel was made in October 2018 for irradiation at Advanced Test Reactor (ATR).
- Barrier development against Fuel-Cladding Chemical Interaction (FCCI). FCCI is a phenomenon where fission products (typically lanthanides) diffuse into the fuel cladding steel and embrittle the cladding. FCCI depends in part on time at temperature. A practical long lifetime TWR fuel pin requires a barrier between the fuel and the cladding. Various materials and manufacturing methods are being explored to develop effective barriers against FCCI, followed by diffusion tests in laboratory furnaces and irradiation testing in ATR to verify performance.
- Metal fuel irradiation at ATR. ATR is used to obtain early performance verification of innovations in the metal fuel design. Cadmium shrouds are used to eliminate 99% of thermal neutrons to simulate a fast reactor neutron environment. Irradiation of advanced fuel rodlets started in November 2013 and of sodium bonded fuel in July 2019. Two specimens of advanced fuel were discharged at 4% burnup and PIE was completed confirming excellent performance of FCCI barrier and as predicted filling of the inner hole with porous fuel—see [Fig. 11](#). Two additional specimens were discharged at 6% burnup and are undergoing PIE while a fifth rodlet is undergoing irradiation to 15% burnup. After these early tests, fuel assembly irradiation tests will ultimately be performed in a fast test reactor under prototypical flux and dose conditions. The purpose of the test of sodium bonded metal fuel is to confirm consistency of irradiation performance of newly manufactured/extruded fuel with historic injection cast fuel.
- Transient performance of ferritic martensitic steel clad fuel pins. Transient performance data for validation of fuel performance models are key for licensing of metal fuel, especially during overpower transients. The Transient Reactor Test Facility (TREAT) at Idaho National Laboratory (INL) was recently restarted, and TerraPower, LLC is performing design and testing of a new sodium loop in collaboration with DOE to support transient testing of irradiated fuel pins from FFTF and advanced fuel pins.

¹⁴Barrier protecting cladding material from chemical interaction with lanthanide fission products.

¹⁵An alloy of uranium with 10 wt% Zirconium.

Fig. 11 Schematic of as fabricated (left) and irradiated (right) TerraPower advanced metallic fuel. PIE of fuel irradiated to 4% burnup confirms expected closure of central voided space with porous fuel and shows no signs of FCCI.

- Optimization and testing of optimized ferritic martensitic steel for cladding and ducts. Studies of material characteristics and former industry experience has resulted in the selection of ferritic martensitic steels, with HT9 as the primary candidate. To improve understanding of HT9 irradiation behavior, five different heats of archived HT9 samples from the FFTF irradiation programs were characterized. The data has enabled completion of an optimization program of the HT9 microstructure with the goal of improved irradiation performance, while remaining within the original HT9 specification; a critical distinction that allows historical irradiation data of HT9 to be used for qualification and licensing. Heavy ion irradiation of HT9 up to 600 dpa was performed to measure swelling behavior. While heavy ion irradiations are not capable of emulating all aspects of neutron induced irradiation damage, they have proven successful in replicating specific radiation effects such as swelling. [Fig. 4](#) shows substantial reduction of void swelling for TerraPower's optimized HT9 versus that of archived HT9 samples. Mechanical testing also confirmed that improved microstructure in optimized HT9 led to performance improvements of mechanical properties. Lessons learned from HT optimization were used to produce heats of other ferritic martensitic steels for both heavy ion and neutron irradiations. Over 1000 samples, including FFTF HT9 already irradiated to 155 dpa, as well as TerraPower optimized HT9, and advanced steels have been irradiated in the BOR-60 reactor ([Izhutov et al., 2015](#)). A supply chain for the optimized HT9 has also been developed. More than 8 MT of HT9 has been manufactured to support development and qualification activities, and a network of domestic and international suppliers has been created. Cladding tubes have been produced with multiple suppliers; successful production of ducts using stainless steel 410 has been demonstrated and duct manufacturing process development work using HT9 is currently underway.

In parallel with fuel and structural material development, work has been also performed on other primary and intermediate system components and equipment, such as core support structure, sodium pumps, intermediate heat exchangers, to evaluate their Technology Readiness Levels (TRLs) to provide guidance for development, testing, and the equipment qualification program. TerraPower, LLC has contracted with more than 50 industrial, national laboratories and academic institutions to address these needs including selected proof of manufacturing activities, such as FCCI barriers, fuel extrusion, HT9 ducts or manufacturing of full size fuel assembly. This is coupled with in-house testing to progressively reduce risk and advance TRLs. Selected examples are given in [Gilleland et al. \(2016\)](#). Significant development is also ongoing on computer codes for TWR performance and safety analyses and their qualifications. These are discussed in [Touran et al. \(2017\)](#).

Even with the robust fuel and material development program, the first TWR plants to be built will not be operating in equilibrium on depleted uranium. Rather, a stepwise approach to the deployment of TWR plants will be used where early plants will use medium assay low enriched uranium feed and non-vented fuel operated to lower peak burnups than 30%. As data and experience with operation and performance of TWR cores is accumulated, burnups will be increased while reload enrichment will be decreased in successive TWR units to ultimately reach the operation on depleted uranium reloads. Also, some aspects such as core radial expansion/bowing reactivity feedbacks, operating performance of passive reactivity devices need to be validated in a prototype or demonstration reactor. TerraPower, LLC first developed a conceptual design of 600MWe prototype reactor TWR-P to demonstrate the breed-and-burn process in a flux profile and shuffling scheme similar to a commercial TWR core, to validate the overall core performance and key characteristics and accommodate lead test assemblies to qualify fuel for commercial design. This was followed later at the request of an international customer with a conceptual design of a 300MWe version. Currently, TerraPower, LLC is focusing on the development of demonstration and commercial versions of TWR-IES plants coupled to salt storage technology

to accommodate rapid load following needs in grids with large penetration of renewables and cost reduction to be competitive with natural gas, while providing clean energy beyond electricity only.

Glossary

Breed-and-burn reactor Reactor whose criticality is maintained only with bred fissile material.

Burnable poisons (BP) Materials that have a high neutron absorption cross section that are converted into materials of relatively low absorption cross section as the result of neutron absorption. To control large amounts of excess fuel reactivity without control rods, they are loaded into the core.

Burnup A measure of the amount of fission energy released from a given quantity of fuel. It is proportional to the neutron fluence with good accuracy.

Cladding The structural material that separates the nuclear fuel from the coolant.

Neutron economy The balanced account of the neutrons created and lost in a reactor. For more excess neutrons which can be utilized for breeding, it is said better neutron economy.

Neutron fluence The neutron flux integrated over a time period.

Neutron flux Number of neutrons crossing a unit area per second. Reaction rates, such as the fission rate, are proportional to the neutron flux.

Neutron spectrum The neutron flux energy distribution.

TRISO Tri-isotropic coated fuel particles which have been developed for HTGR.

Abbreviations

BOC/EOC Beginning/end of cycle

 LFR Lead and/or LBE cooled fast reactor
 MOTTO cycle Multichannel once-through-then-out cycle
 SFR Sodium-cooled fast reactor

Introductions

A future ideal nuclear energy system

An advanced civilized society involves a large amount of energy consumption. Since the industrial revolution, mankind has met this demand for energy through the massive consumption of fossil fuels. We have been worried about the depletion of resources, but global warming and climate change due to the massive release of carbon dioxide gas are now more pressing issues, and there is a consensus to try to avoid using them. Renewable energies, especially solar energy and wind power, are expected. However, power they can generate is greatly influenced by the weather and fluctuates with time. Therefore, it is attempted to store energy with a battery or the like. However, storing energy increases the cost of energy considerably.

Nuclear power does not release carbon dioxide, and a breeder reactor can solve resource problems. However, as shown in Fig. 1, there is a problem of the technologies common to atomic bomb and a problem of the production of radioactive materials (Sekimoto, 2010b).

The technologies common to atomic bomb causes the problem of nuclear proliferation in terms of nations and the problem of physical protection in terms of terrorists. The production of radioactive materials also causes problems with accidents when the reactor is in operation, and wastes problems even after the operation is over. The risk of these problems cannot be reduced to zero, but can be reduced to an acceptable level by properly designing the nuclear system. These problems must be solved within an economic tolerance. There are many problems, and the researches on advanced nuclear reactors are trying to solve some of these, but no reactor has yet been proposed that can solve all of them simultaneously. Section “How CANDLE reactors satisfy the requirements for future ideal nuclear energy system” explains how the CANDLE reactor can solve these problems.

What is the CANDLE reactor concept?

Concept of the CANDLE burning strategy

CANDLE stands for Constant Axial shape of **Neutron flux**, nuclide densities and power profile During Life of Energy production (Sekimoto and Ryu, 2000a). This acronym also implies candle-like **burnup**. When this burnup strategy is employed, the fissioning region propagates along the core axis at a speed proportional to the power output without changing the spatial distributions of the nuclide densities, neutron flux, and power density. Significantly, unlike conventional reactor designs, it is not necessary to equip movable components for burnup control (e.g., control rods and control reflector), despite the fuel being fixed in the core. Sekimoto (2010a) has written a book on this topic for general readers, which has a Chinese translation (Zhang and Guo, 2014).

The infinite neutron multiplication factor, k_{∞} , of the CANDLE reactor fuel varies with increasing **neutron fluence** or fuel burnup in the manner shown in Fig. 2A and in (Qvist, 2021). It is less than unity for the fresh fuel, but increases with increasing burnup, eventually exceeding unity. After reaching a maximum, it decreases, becoming less than unity again. k_{∞} becomes unity at $B = B_1$ and B_3 , where B is the burnup. B_4 is the maximum attained burnup.

Fig. 2B plots the same data along the core axis. k_{∞} increases with burnup on the left side of the peak, and decreases on the right side. Consequently, the peak is shifted to the left (i.e., to the fresh fuel side) with burnup. In this Chapter, we will consider a vertical core and the peak is shifted to the bottom.

Fig. 1 Problems associated with nuclear energy.

Fig. 2 Infinite-medium neutron multiplication factor variations in CANDLE fast reactor core. (A) Plotted against fuel burnup. The graph is for the infinite core. k_{eff} and B_2 are entered for the later explanation for the finite core. (B) Plotted along the central axis (z-axis). Arrows indicate the directions of shift with burnup.

Fig. 3 Refueling in the CANDLE burnup strategy. From Sekimoto H (2010a) *Light a CANDLE*, 2nd edn., Tokyo, Japan: CRINES, Tokyo Tech. ISBN: 978-4-905205-00-5 C3053 E. Retrieved from https://www.researchgate.net/publication/305391375_Light_a_CANDLE_2nd_ed.

Although the power density level at a given axial location in the core varies, the shape of the power distribution remains constant. The burning region moving speed is proportional to the power level; the principle behind this is explained mathematically in section “**Mathematical explanation of CANDLE burning**”.

In reality, the core height is finite. When the burning region reaches the end of the core, the spent fuel should be removed from the top of the core, and adding fresh fuel at the bottom of the core as shown in Fig. 3. In this way, CANDLE burning can be sustained.

This refueling scheme is realized by cutting the fuel pins into several pieces. It is also possible by using a pebble-bed reactor (Ryu and Sekimoto, 2000).

Here we will consider k_{eff} expected for different discharge burnup. Since the relationship between fuel burnup and k_{∞} at different axial position for finite cores is almost the same for the infinite core, we will use Fig. 2A for our consideration. Now we consider the horizontal axis of this figure as the discharge burnup. The effective neutron multiplication factor, k_{eff} , of the core is less than unity for the fresh fuel ($B = 0$), but increases with increasing discharge burnup, and becomes unity at $B = B_2$, where $B_2 > B_1$. It continues to increase with increasing discharge burnup and takes its maximum, and then it decreases. It becomes unity again at $B = B_4$, where $B_4 > B_3$. If the neutron economy of the core becomes better, B_2 becomes smaller and B_4 becomes larger.

The discharge burnup B must be selected to satisfy $B_2 \leq B \leq B_4$. When the spent fuel is not discharged, the spent fuel burnup takes its maximum value B_4 . If we try to use uranium effectively, B_4 is preferred for the discharge burnup. However, the maximum permissible burnup for the fuel is usually much less than B_4 to satisfy material integrity, and we will consider B_2 later.

The following subsections describe two examples of CANDLE burning: one for a fast reactor and the other for a thermal reactor.

Fast reactors

When the average neutron energy of the neutron spectrum is high, it is called hard spectrum. Hard-spectrum fast reactors have excellent neutron economy. CANDLE burning was tried for these reactors using natural or depleted uranium as fresh fuel (Sekimoto and Ryu, 2000a,b; Sekimoto et al., 2001).

^{238}U in the fresh fuel absorbs neutrons and becomes ^{239}Pu . ^{239}Pu density of the fresh fuel is zero, but increases with burnup. Eventually it becomes saturated, where the production rate of ^{239}Pu is equal to its destruction rate, and the ratio of nuclide number density of ^{239}Pu to ^{238}U is constant. On the other hand, the total FP density increases with burnup. Therefore, at high burnups k_{∞} drops with burnup as seen in Fig. 2.

Since natural uranium is highly subcritical, many neutrons need to be absorbed by ^{238}U to produce a large amount of ^{239}Pu to bring the system into a critical state. Thus, it is important to use a nuclear reactor that has an excellent neutron economy. The fuel burnup is increased by supplying many neutrons to the fresh fuel. This results in a high burnup of spent fuel and considerably reduces the burning region moving speed. Edward Teller proposed a similar idea (Teller et al., 1996; Hyde et al., 2008) using thorium. However, CANDLE burning cannot be achieved in the truest sense when only thorium is used.

A possibility of the pebble-bed fast reactor for CANDLE burning was numerically demonstrated using natural uranium as a fresh fuel (Ryu and Sekimoto, 2000).

Thermal reactors with burnable poison

In the case of a fast CANDLE reactor, the average burnup of the spent fuel is as large as 40%FIMA (Fissions per Initial Heavy Metal Atoms). From now on, %FIMA is simply written as %. 40% is a great advantage in terms of effective use of natural uranium, but there is no fuel element that can withstand such a high burnup in the current fast reactor design. How to solve this problem is described in section "Solving high burnup problems". Apart from this, this subsection describes tri-isotropic (TRISO) coated fuel particles (Sawa et al., 1996), which have been developed as a fuel that can withstand such high burnup.

Since this fuel has a large parasitic neutron absorption and neutron slowing-down, it cannot be used in the fast CANDLE reactor, but used as a normal fuel in a High Temperature Gas cooled Reactor (HTGR). In fact, a CANDLE burning HTGR had been proposed (van Dam, 1998; Ohoka and Sekimoto, 2004). By using enriched uranium fuel with burnable poisons (BP), k_∞ can be varied as shown in Fig. 2.

By increasing the uranium enrichment and gadolinium BP concentration, the burnup of the spent fuel can be increased. Although it can be used as a long-life reactor for special purposes, it is not a **breed-and-burn reactor** and will not be discussed further in this chapter.

Mathematical explanation of CANDLE burning

Some principles and characteristics of the CANDLE burning are easy to understand when they are mathematically explained. In this section, a steady state CANDLE burning equation is derived from basic equations of neutron transport and fuel burnup, and derive some relations among important parameters by using approximate treatment.

Basic equations of neutron transport and fuel burnup (Sekimoto et al., 2001)

For the investigation of CANDLE burning, we have to treat both neutron flux, $\phi(\vec{r}, \vec{\Omega}, E, t)$, and nuclide number density distributions, $n_j(\vec{r}, t)$, as dependent variables. The variables t and $\vec{r}$ are time and position in three dimensional space, respectively, and E and $\vec{\Omega}$ are energy and direction of motion of neutron, respectively. The neutron flux satisfies the following neutron transport equation:

$$\begin{aligned} & \frac{1}{v} \frac{\partial}{\partial t} \phi(\vec{r}, \vec{\Omega}, E, t) + \vec{\Omega} \cdot \nabla \phi(\vec{r}, \vec{\Omega}, E, t) + \sum_j n_j(\vec{r}, t) \sigma_{T,j}(E) \phi(\vec{r}, \vec{\Omega}, E, t) \\ &= \int_0^\infty dE' \int_{4\pi} d\vec{\Omega}' \sum_j n_j(\vec{r}, t) \sigma_{S,j}(\vec{\Omega}' \cdot \vec{\Omega}, E' \rightarrow E) \phi(\vec{r}, \vec{\Omega}', E', t) \\ &+ \frac{1}{4\pi} \int_0^\infty dE' \int_{4\pi} d\vec{\Omega}' \sum_j n_j(\vec{r}, t) \chi(E) \nu_j (1 - \beta_j) \sigma_{F,j}(E') \phi(\vec{r}, \vec{\Omega}', E', t) \\ &+ \sum_i \frac{\chi_i(E)}{4\pi} \lambda_i c_i(\vec{r}, t) + s(\vec{r}, \vec{\Omega}, E, t) \end{aligned} \quad (1)$$

where

- v : velocity of the neutron with energy E ,
- $\sigma_{T,j}(E)$: microscopic total cross-section of nuclide j for the neutron with energy E ,
- $\sigma_{S,j}(\vec{\Omega}' \cdot \vec{\Omega}, E' \rightarrow E)$: microscopic scattering cross-section of the nuclide j for the neutron with energy E' and direction $\vec{\Omega}'$ transferred to E and $\vec{\Omega}$. This reaction includes any neutron emitting reactions except fission,
- $\sigma_{F,j}(E)$: microscopic fission cross-section of the nuclide j for the neutron with energy E ,
- ν_j : average number of neutrons emitted by the fission of nuclide j ,
- $\chi(E)$: prompt fission neutron energy spectrum,
- $\chi_i(E)$: delayed neutron energy spectrum for the precursor i ,
- β_j : delayed neutron precursor fraction produced by the fission of nuclide j ,
- λ_i : decay constant of the delayed neutron precursor i ,
- $c_i(\vec{r}, t)$: number density of the delayed neutron precursor i ,
- $s(\vec{r}, \vec{\Omega}, E, t)$: external neutron source.

Although $\chi(E)\nu_j(1 - \beta_j)$ is a function of the energy, E' , of impinging neutron which causes the fission, this dependence is omitted for simplicity.

The delayed neutron precursor density $c_i(\vec{r}, t)$ satisfies the following equation:

$$\frac{\partial}{\partial t} c_i(\vec{r}, t) + \lambda_i c_i(\vec{r}, t) = \int_0^\infty dE' \int_{4\pi} d\vec{\Omega}' \sum_j n_j(\vec{r}, t) \beta_{ij} \nu_j \sigma_{F,j}(E') \phi(\vec{r}, \vec{\Omega}', E', t) \quad (2)$$

where

$\beta_{i,j}$: fraction of delayed neutron precursor i produced by the fission of nuclide j , which satisfies

$$\beta_j = \sum_i \beta_{i,j} \quad (3)$$

The nuclide density satisfies the following equation:

$$\frac{\partial}{\partial t} n_j(\vec{r}, t) = -n_j(\vec{r}, t) \left(\lambda_j + \int_0^\infty dE' \sigma_{A,j}(E') \int_{4\pi} d\vec{\Omega}' \phi(\vec{r}, \vec{\Omega}', E', t) \right) + \sum_k n_k(\vec{r}, t) \left(\lambda_{k \rightarrow j} + \int_0^\infty dE' \sigma_{k \rightarrow j}(E') \int_{4\pi} d\vec{\Omega}' \phi(\vec{r}, \vec{\Omega}', E', t) \right) \quad (4)$$

where

$\sigma_{A,j}(E)$: microscopic absorption (including transmutation) cross-section of nuclide j for the neutron with energy E ,

$\sigma_{k \rightarrow j}(E)$: microscopic neutron cross-section of nuclide k that is transmuted into nuclide j ,

λ_j : decay constant of nuclide j ,

$\lambda_{k \rightarrow j}$: decay constant of nuclide k that is transmuted to nuclide j .

Here the nuclide j covers both actinides and FPs produced from the fuel. The production of FP from fission can also be treated by Eq. (4) by choosing $\sigma_{k \rightarrow j}(E)$ properly.

In addition to these equations we consider the equations of temperature and motion of materials. Coolant flow distribution affects strongly temperature distributions, and the temperature distributions affect effective microscopic cross sections and material densities and shapes (Sekimoto and Udagawa, 2006).

Steady state CANDLE burning equation (Sekimoto et al., 2001)

In the steady state CANDLE burning case, the reactor is in a critical state and the external neutron source does not stay in the core. Only time dependent phenomena considered is the burnup. In this situation the time derivative of neutron flux in Eq. (1) and the time derivative of delayed neutron precursor density in Eq. (2) can be neglected. These two equations can be combined to the following equation:

$$\begin{aligned} \vec{\Omega} \cdot \nabla \phi(\vec{r}, \vec{\Omega}, E, t) + \sum_j n_j(\vec{r}, t) \sigma_{T,j}(E) \phi(\vec{r}, \vec{\Omega}, E, t) = \int_0^\infty dE' \int_{4\pi} d\vec{\Omega}' \sum_j n_j(\vec{r}, t) \sigma_{S,j}(\vec{\Omega}' \cdot \vec{\Omega}, E' \rightarrow E) \phi(\vec{r}, \vec{\Omega}', E', t) \\ + \frac{1}{4\pi k_{eff}} \int_0^\infty dE' \int_{4\pi} d\vec{\Omega}' \sum_j n_j(\vec{r}, t) \chi_j(E) \nu_j \sigma_{F,j}(E') \phi(\vec{r}, \vec{\Omega}', E', t) \end{aligned} \quad (5)$$

Here the reactor is usually kept critical by adjusting the control rods. However, it is complicated to implement this procedure in neutron transport equation, and the eigenvalue k_{eff} is introduced instead. The reactor is controlled to produce the designed total power output, $P(t)$:

$$\Gamma \int_{Core} d\vec{r} \int_0^\infty dE' \int_{4\pi} d\vec{\Omega}' \sum_j n_j(\vec{r}, t) \sigma_{F,j}(E') \phi(\vec{r}, \vec{\Omega}', E', t) = P(t) \quad (6)$$

where $\int_{Core} \bullet d\vec{r}$ denotes the integration over the whole core, and Γ is the energy released per fission.

The basic equations for our study are Eqs. (4), (5), (6).

The ideal CANDLE burning can be realized for core geometries where the core length is infinite and the geometry perpendicular to the core axis is the same at different axial positions. We also assume a constant power operation and Eq. (6) becomes

$$\Gamma \int_{Core} d\vec{r} \int_0^\infty dE' \int_{4\pi} d\vec{\Omega}' \sum_j n_j(\vec{r}, t) \sigma_{F,j}(E') \phi(\vec{r}, \vec{\Omega}', E', t) = P_0 \quad (7)$$

In this scenario the neutron flux shape and nuclide densities move with burnup, whose relative shapes are not changed and their positions move with a constant speed V along z -axis for CANDLE burning. For this burnup scheme, when the following Galilean transformation (Goldstein, 1950) given by

$$\vec{r}_G = \vec{r} + \vec{V}t \quad (x_G = x, \quad y_G = y, \quad z_G = z + Vt) \quad (8)$$

$$t_G = t \quad (9)$$

is applied to Eqs. (4), (5), (7), and by replacing the variable $\vec{r}_G$ and t_G by $\vec{r}$ and t , respectively, then these equations will be changed to

$$V \frac{\partial}{\partial z} n_j(\vec{r}) = -n_j(\vec{r}) \left(\lambda_j + \int_0^\infty \sigma_{A,j}(E') \phi(\vec{r}, E') dE' \right) + \sum_k n_k(\vec{r}) \left(\lambda_{k \rightarrow j} + \int_0^\infty \sigma_{k \rightarrow j}(E') \phi(\vec{r}, E') dE' \right) \quad (10)$$

$$\begin{aligned} \vec{\Omega} \cdot \nabla \phi(\vec{r}, \vec{\Omega}, E) + \sum_j n_j(\vec{r}) \sigma_{T,j}(E) \phi(\vec{r}, \vec{\Omega}, E) &= \int_0^\infty dE' \int_{4\pi} d\vec{\Omega}' \sum_j n_j(\vec{r}) \sigma_{S,j}(\vec{\Omega}' \cdot \vec{\Omega}, E' \rightarrow E) \phi(\vec{r}, \vec{\Omega}', E') \\ &+ \frac{1}{4\pi k_{eff}} \int_0^\infty dE' \int_{4\pi} d\vec{\Omega}' \sum_j n_j(\vec{r}) \chi_j(E) \nu_j \sigma_{F,j}(E') \phi(\vec{r}, \vec{\Omega}', E') \end{aligned} \quad (11)$$

and

$$\Gamma \int_{Core} d\vec{r} \int_0^\infty \sum_j n_j(\vec{r}) \sigma_{F,j}(E) \phi(\vec{r}, E) dE = P_0 \quad (12)$$

where we have used the scalar flux, $\phi(\vec{r}, E)$, which is defined by

$$\phi(\vec{r}, E) \equiv \int_{4\pi} \phi(\vec{r}, \vec{\Omega}, E) d\vec{\Omega} \quad (13)$$

In many cases, we can ignore radioactive decay in Eq. (10). Usually the decay of ^{241}Pu and some FPs may contribute some, but their contribution to k_{eff} is almost negligible. In this case Eq. (10) becomes

$$V \frac{\partial}{\partial z} n_j(\vec{r}) = -n_j(\vec{r}) \int_0^\infty \sigma_{A,j}(E') \phi(\vec{r}, E') dE' + \sum_k n_k(\vec{r}) \int_0^\infty \sigma_{k \rightarrow j}(E') \phi(\vec{r}, E') dE' \quad (14)$$

If $\phi(\vec{r}, E)$ and $n_j(\vec{r})$ are the solution of Eqs. (11)–(14), $\alpha \phi(\vec{r}, E)$ and $n_j(\vec{r})$ are also the solution of these equations for αV instead of V , and for αP_0 instead of P_0 . It means that if the power level is changed, the relative power shape does not change but only power level and burning region speed change by that rate.

Approximated treatment

Here, we will use one-speed diffusion approximation (Bell and Glasstone, 1970). Eq. (14) suggests that each nuclide density can be expressed by using neutron fluence, θ , where

$$\theta(z) = \int_{-\infty}^z \phi(z') \frac{dz'}{V} \quad (15)$$

It is rewritten as

$$\phi(z) = V \frac{d\theta(z)}{dz} \quad (16)$$

Therefore, k_∞ can be also written as dependent on θ . By using the one-group diffusion approximation, Eq. (11) can be written as

$$-L^2 \frac{d^2}{dz^2} \phi(z) + \phi(z) = \frac{k_\infty(\theta(z))}{k_{eff}} \phi(z) \quad (17)$$

where L is the diffusion length.

In order to obtain a simple analytical solution, van Dam (2000) approximates $k_\infty(\theta)$ as

$$k_\infty(\theta) = -4(k_{max} - k_{min}) \left(\frac{\theta}{\theta_M} \right)^2 + 4(k_{max} - k_{min}) \left(\frac{\theta}{\theta_M} \right) + k_{min} \quad (18)$$

$k_\infty(\theta)$ has the value k_{min} at $\theta = 0$ and θ_M , and its maximum value k_{max} at $\theta = \theta_M/2$. Using Eqs. (16), (18), the solution of Eq. (17) is given by

$$\theta(z) = \theta_M \frac{1}{1 + e^{-\alpha z}} \quad (19)$$

where the axial position is chosen so that the flux peak position locates at $z = 0$. The flux is given by

$$\phi(z) = V \theta_M \alpha \frac{1}{(1 + e^{-\alpha z})(1 + e^{\alpha z})} \quad (20)$$

where α is related to the half width, W , of flux shape as

$$W = \frac{2 \ln(3 + 2\sqrt{2})}{\alpha} = \frac{3.53}{\alpha} \quad (21)$$

k_{max} and k_{min} are expressed by using α as

$$\frac{k_{max}}{k_{eff}} = 1 + \frac{1}{2} L^2 \alpha^2 \quad (22)$$

$$\frac{k_{min}}{k_{eff}} = 1 - \frac{1}{2} L^2 \alpha^2 \quad (23)$$

From Eqs. (21), (22)

$$W = \frac{2.49L}{\sqrt{\frac{k_{max}}{k_{eff}} - 1}} \quad (24)$$

From this equation W is decreased by decreasing L and/or increasing k_{max} .

The maximum value of flux, ϕ_{max} , is given from Eq. (20) as

$$\phi_{max} = \frac{1}{4} V \theta_M \alpha = 0.88 \frac{V \theta_M}{W} \quad (25)$$

Therefore, the velocity of burning region is determined as

$$V = 1.13 \frac{\phi_{max}}{\theta_M} W \quad (26)$$

This equation is easy to be understood from the physical meaning of θ_M/ϕ_{max} and W/V . As already mentioned, the burnup of spent fuel for CANDLE reactor is very high. It means θ_M is very large and therefore V is very small.

Chen et al. (2012) extend the approximated treatment including a few important actinide nuclides.

Typical examples of the CANDLE reactor (parametric survey)

Though both fast and thermal CANDLE reactors were considered in the previous sections, the following sections focus only on fast CANDLE reactors. Even when discussing fast CANDLE reactors, there are many different designs that can be considered; for example, several kinds of fuels and coolants can be used, and the core designs can be varied. This section shows how the performance of fast CANDLE reactors vary when fundamental parameters are varied (Sekimoto and Ryu, 2000b; Sekimoto, 2001). The performances are compared in the equilibrium state. Table 1 shows the reference reactor design parameters.

The core is cylindrical with a radius of 2 m and an infinite height. However, setting the core height to infinity is not possible in practical calculations, so instead it was set to 8 m. When the core height used in the calculation is sufficiently large that the neutron flux and leakage are negligibly small at the upper and lower boundary of the core, the neutron flux distribution in the burning region will be unaffected by a change in the core boundaries and all other distributions can be considered as those for an infinitely long core. Furthermore, it was confirmed by investigating the effects of changing the boundary conditions from vacuum to reflective conditions.

Natural uranium was used as the fresh fuel. Since CANDLE burning requires an excellent neutron economy, a lead-bismuth-eutectic (LBE) cooled metallic fueled reactor was used for the reference reactor. The percentage of fuel volume (excluding cladding) was set to 50%, which is larger than that in current reactors; this increases the neutron economy but reduces the cooling capacity.

Table 1 Design parameters of reference reactor design.

Reactor	Thermal output	3000 MWt
	Core radius	200 cm
	Radial reflector thickness	50 cm
Fuel pin	Fuel form	U-10w%Zr
	Fuel pellet diameter	0.8 cm
	Cladding tube material	HT-9
	Cladding tube thickness	0.035 cm
Coolant		Pb-Bi (44.5%, 55.5%)
Fuel volume fraction (excluding cladding)		50%

Table 2 Effective neutron multiplication factor, burning region moving speed, and spent fuel burnup for various core design parameters.

(A) For different fuels				
Fuel	Oxide	Nitride	Metal	
Effective neutron multiplication factor	0.926	0.990	1.015	
Moving speed of burning region	4.7 cm/year	3.5 cm/year	3.8 cm/year	
Average burnup of spent fuel	452 GWd/t	445 GWd/t	426 GWd/t

(A) and (B) From Sekimoto H (2001) Applications of "CANDLE" burnup strategy to several reactors, ARWIF-2001. Chester, UK.; (C) and (D) From Sekimoto H and Ryu K (2000b). Feasibility study on the CANDLE new burnup strategy. *Transactions of the American Nuclear Society* 82: 207–208.

The fuel and coolant materials, fuel volume fraction, and core radius are varied, and the effective neutron multiplication factor, k_{eff} , the burning region moving speed, V , and the average burnup of spent fuel are calculated and shown in **Table 2**. The value of V is very low—about 4 cm/year in all cases. The average burnup of spent fuel was extremely high—about 400 GWd/t, which indicates that about 40% of the loaded fuel was burnt.

Table 2A shows that only the k_{eff} of the metallic fuel exceeds unity. It is clearly difficult to realize CANDLE burning using oxide fuel, whereas it may be possible with a little effort using nitride fuel. Both V and the average burnup of spent fuel differ for different fuels, but V varies more. This large variation in V is attributed to the different fissile material densities of the fuels.

Table 2B shows that k_{eff} also varies for different coolants. The differences are mostly attributed to the different neutron economies of the coolants. Helium has the highest k_{eff} and sodium has the lowest k_{eff} . However, the differences are not significant and CANDLE burning is possible for any coolant when a metallic fuel is used. The cooling performance of sodium is better than of the other coolants, and it will be often employed in the following parts of this chapter.

Coolants with low neutron slowing-down and absorbing powers are suitable for fast reactors. A large scattering cross section is desirable for small reactors since it results in effective neutron confinement. Since lead and LBE are better in terms of these parameters than sodium, they have been used as coolants for small long-life fast reactors (Sekimoto and Zaki, 1995). Previous lead- or LBE-cooled small long-life reactors employ natural lead for economic reasons, but natural lead contains several isotopes. On the other hand, ^{208}Pb , whose isotopic abundance is 52.4%, is a double magic nucleus and has a much smaller capture cross section and a higher threshold energy of inelastic scattering than the other isotopes of natural lead. An economical separation of this isotope has been proposed (Khorasanov, 2013). A ^{208}Pb -cooled metallic fuel fast reactor is expected to have a harder neutron spectrum than natural-lead-cooled (Okawa and Sekimoto, 2010). The void reactivity coefficient shifts in the negative direction when ^{208}Pb is used as a coolant, since the spectrum hardening effect by coolant voiding becomes small. Sekimoto and Nakayama (2014) changed the void coefficient in a medium-sized CANDLE reactor from \$ 7.94 to \$ 3.09 by changing the coolant from sodium to ^{238}Pb . When CANDLE reactors are improved by design change, the ^{208}Pb coolant can further improve their performance. They are explained later in section "Characteristics of CANDLE reactor".

The effect of fuel volume fraction is shown in **Table 2C**. When the fuel volume fraction is large, k_{eff} is large so that CANDLE burning can be realized more easily. The change in V is inversely proportional to the fuel volume fraction, but the average burnup of spent fuel does not change for different fuel volume fractions.

Table 2D shows that the core radius also exerts a considerable influence. When the core radius is large, k_{eff} is large so that CANDLE burning can be realized more easily. However, neither V nor the average burnup of spent fuel changes for different core radii.

The properties of CANDLE burning obtained here by numerical simulation are consistent with the properties derived mathematically in the previous section.

Startup of CANDLE burning

The above demonstrations of CANDLE burning only considered equilibrium steady states since they typically exhibit CANDLE characteristics. However, the equilibrium core contains many radioactive materials including higher actinides and FPs. It may thus seem to be difficult to construct the initial core, but there are several methods for overcoming these problems.

The initial core may be realized by supplying a sufficient number of neutrons from an external neutron source (Teller et al., 1996). However, this method is expensive and the power profile varies drastically in the early stages of the first cycle. By using enriched uranium (Sekimoto and Miyashita, 2006) and/or plutonium (Sekimoto et al., 2003) substituted for actinides in the equilibrium core, it may be possible to construct an initial core that has a similar power profile to the equilibrium profile and that can reach an equilibrium state without any drastic changes.

The isotopic fraction of plutonium (plutonium vector) varies for different spent fuels, which makes it difficult to construct the first core for CANDLE burning using plutonium from spent fuel. On the other hand, uranium enrichment can be precisely controlled and makes it easier to construct the first core (Sekimoto and Miyashita, 2006). Fig. 4A shows the axial nuclide number densities of ^{235}U and ^{238}U . The maximum enrichment is about 13% at an axial position of about 350–400 cm, which is well below the constraint of 20%. The power profile remains almost constant along operation time as shown in Fig. 4B, but it shifts at a constant speed in the negative axial direction, as expected.

Characteristics of CANDLE reactor

Advantageous characteristics (Sekimoto et al., 2001; Sekimoto, 2010a)

The advantages of using CANDLE burning in a fast reactor with an excellent neutron economy are summarized. The items discussed here will be further discussed in section “How CANDLE reactors satisfy the requirements for future ideal nuclear energy system”.

- No fissile material is required except for the initial core.
Accordingly, if the initial core can be constructed, no enrichment or reprocessing facilities are required. This feature is common to breed-and-burn fast reactors (Qvist, 2021).
- There is no need to control burnup excess reactivity.
Accordingly, it is not necessary to equip movable components for burnup control such as shim control rods.
- The average burnup of spent fuel is about 40%.

About 40% of natural (or depleted) uranium fissions to generate energy. For a simple once-through cycle, the energy extracted from natural uranium is about 50 times greater than in presently used LWRs, and the volume of spent fuel for geological disposal will be one-eighth of LWRs with 4% enriched uranium fuel (5% discharge burnup) per unit energy production. Miscellaneous waste, especially which associated with fuel cycle, will also be extremely small.

Fig. 4 Startup of CANDLE burning using enriched uranium. (A) Nuclide number densities of ^{235}U and ^{238}U as functions of position along the initial core axis. (B) Power density distributions for four different burnup durations. From Sekimoto H and Miyashita S (2006) Startup of “candle” burnup in fast reactor from enriched uranium core. *Energy Conversion and Management* 47(17): 2772–2780.

- The speed of burning region, V , is about 4 cm/year.
This extremely slow speed makes it easy to design a long-life reactor. For example, to increase the core life by 20 years, the core height just needs to be increased by only 0.8 m.
- Even in case of a core disruptive accident (CDA), it is less likely for a recriticality accident to happen.
There is no excess fissile material in the core to produce excess reactivity, and no need for neutron absorber to suppress it. And the amount of coolant, which suppresses k_{eff} , is smaller than the conventional fast reactors. Therefore, when the core is disrupted and fuel rearrangement occurs, it is less likely to lead to a recriticality accident. Even if it happens, the induced excess reactivity is expected to be much less than in conventional fast reactors.
- The number density distribution of each nuclide does not change due to fuel burnup.
The number density distribution of each nuclide does not change due to fuel burnup but only shifts along the core axis. Therefore, the reactor characteristics such as power peaking and power coefficient of reactivity do not change due to fuel burnup. Therefore, the estimation of core condition becomes very reliable. The reactor operation strategy remains un-changed for the entire core life.
- The radial power shape is very smooth.
The power density distribution is smooth, and does not change due to fuel burnup but only shifts along the core axis. In conventional reactors, even if the radial power profile is optimized at the beginning, it will change along burnup. This is not the case for CANDLE. Therefore, it is possible to highly optimize the radial power distribution. This is explained in more detail in section “**Power density flattening and core height shortening**”. This can increase the energy output from the core.

Problematic characteristics (Sekimoto et al., 2001; Sekimoto, 2010a)

As mentioned above, the CANDLE reactor has many wonderful properties, but at the same time has the following challenging problems: Some solutions for these problems are given in section “**How to solve the problematic characteristics**”.

- Difficult to establish criticality
As mentioned in section “**Fast reactors**”, in the fast CANDLE reactor, fissile materials to maintain criticality are mostly created by ^{238}U absorbing neutrons in the core. Conventional fast breeder reactors use the same principle, but the criticality can be easily maintained by removing FPs from the core by refueling. On the other hand, in the CANDLE reactor, the burning region moves, so the FPs slowly exits the burning region. This method leaves a significant amount of FPs in the core, which makes it much more difficult to maintain criticality than in conventional fast breeder reactors. This is a big problem. However, we have already introduced some CANDLE core design examples that can achieve criticality.
As burnup increases, FPs accumulate, more neutrons are absorbed into the FPs. In the original CANDLE reactor, where the discharged burnup is taken its maximum limit as shown in Fig. 2A, many neutrons will be absorbed by FPs. Extraction with a lower burnup reduces such parasitic neutron absorption (Toshinsky et al., 1999). A standing-wave breed-and-burn core (Hejzlar et al., 2013; Qvist, 2021) thus facilitates the criticality problem. In the present chapter, a similar approach is adopted for the modified CANDLE described in section “**Solving high burnup problems**”.
- High burnup problems
It is also important to consider ways of controlling the reactor, including power level regulation and shut down. It is important to design a fast reactor that excels in neutron economy and can be operated safely. These will be further explained in detail in section “**How to solve the problematic characteristics**”.
- High burnup problems
For realizing an ideal CANDLE reactor, it is necessary to use materials that can withstand over its maximum discharge burnup, which is usually around 47%. There is currently no fuel element material that can withstand such a high burnup. The volume of accumulated FPs becomes large with high burnup. In this state, the pressure in the fuel element will become excessively high, making it necessary to release gas from there. This necessitates a major design change. Even if the gaseous FPs can be managed, the solid FP volume will also become high, especially when metallic fuel is used; to counteract this, the fresh fuel smear density will need to be reduced. The most severe problem is that current **cladding** can only withstand a burnup much lower than 47%. This problem is discussed in section “**Solving high burnup problems**”. The power flattening, which is discussed in section “**Power density flattening and core height shortening**”, can somewhat alleviate the high burnup problem because the maximum discharge burnup approaches the average discharge burnup.
- Low power density
In the CANDLE reactor, it is necessary to reduce the coolant volume fraction in order to increase the neutron economy. For this reason, the cooling performance is deteriorated and the power density is lowered. The power density is directly related to the economy, and lower density increases the electricity price.

How to solve the problematic characteristics

In the previous section, problematic characteristics are introduced. This section describes how these problems can be mitigated.

Reactor control without control rods

The use of control rods, which consist of shim control rods, regulation control rods and shutdown (scram) rods significantly hurts the neutron economy by reducing the fuel volume fraction in the core and increasing the parasitic neutron absorption. If they are eliminated from the core, it is expected that the neutron economy can be greatly improved. The control rods also disturb power shape. They decrease average power density and deteriorate the economic efficiency. Since CANDLE reactors do not require the shim control rods, only regulation control rods and shutdown rods need to be considered.

- Power level control without control rods (Sekimoto and Nakayama, 2014)

Even without regulation control rods, the power level can be changed by adjusting the coolant flow rate and/or inlet coolant temperature. Three methods shown in Table 3 are considered.

These methods are attempted for two CANDLE reactors, sodium cooled fast reactor (SFR) and ^{208}Pb cooled fast reactor (LFR). The calculation results are shown in Fig. 5, where the outlet coolant temperature is the averaged value over all coolant channels. The results for SFR is shown in (A) and LFR in (B). For both reactors, it can be demonstrated successfully to change the power level from its full power to zero by Method 3 adjusting both coolant flow rate and inlet coolant temperature while the coolant outlet temperature is kept at its designed value. The change of coolant inlet temperature is smaller for LFR.

- Shut-down and start-up by moving some fuel assemblies

Since the shutdown rod is not in the core during power operation, it does not deteriorate the neutron economy due to neutron absorption, but it needs the space for its insertion in the core, thus deteriorating the neutron economy due to neutron leakage. When movable fuel assemblies are introduced and removed at shutdown, the shutdown rods are no longer needed.

A potentially dangerous issue with this system is unplanned insertion of removed fuel during cold shut down state. This problem can be mitigated by removing the fuel downward.

The second issue to consider is that k_{eff} should not increase while removing out the fuel. This is unlikely to happen because the neutron importance profile takes a single peak.

At present, however, the design of this core has not been studied enough.

Table 3 Adjusted and fixed parameters for investigated three methods for power level control without control rods.

	Adjusted parameters	Fixed parameters
Method 1	Coolant flow rate	Coolant inlet temperature
Method 2	Coolant inlet temperature	Coolant flow rate
Method 3	Coolant flow rate Coolant inlet temperature	Coolant outlet temperature

Fig. 5 Inlet and outlet coolant temperatures for different power level for power level control without control rods. (A) Sodium cooled fast CANDLE reactor (SFR). (B) ^{208}Pb cooled fast CANDLE reactor (LFR). From Sekimoto H and Nakayama S (2014) Power level control of CANDLE reactor without control rods. *Annals of Nuclear Energy* 63: 427–431.

Solving high burnup problems

The material integrity of both fuel pellets and cladding should be considered for high burnups. However, since we cannot expect the fuel pellets to remain intact, it is necessary to rely on the cladding integrity. Even in this case, we should be concerned about pellet swelling (especially for metallic fuels) since the swollen pellets may break the cladding. To mitigate this problem, the fuel smear density should be reduced. To ensure the integrity of the fuel pin by means of the cladding, both the displacement per atom (dpa) in the cladding material caused by fast neutrons and the FP gas pressure in the pin should be considered. The dpa is related to the fast neutron (> 0.1 MeV) fluence; its maximum permissible value for HT-9 is about $4.0 \times 10^{23}/\text{cm}^2$, which is much less than that expected for CANDLE burnup ($1.8 \times 10^{24}/\text{cm}^2$). The gas plenum volume necessary for FP gas is much larger than of conventional reactors. The FP gas may be better to be vented from the cladding can.

Replacement of cladding of fuel elements (recladding) and modified CANDLE are tried to solve this problem. These two methods will be described below. Both of these methods are expected to be available in the near future. However, a more ideal approach in the long term is to develop new materials that can withstand high burnup.

- Recladding

This high burnup problems could be solved by recladding after a certain burnup is attained (Hesson et al., 1963; Nagata and Sekimoto, 2007). Two recladding methods are possible. One is a recladding of a whole fuel pin (Nagata et al., 2009), and the other is a recladding of several axial elements of a fuel pin (Karim et al., 2016).

For the metallic fuel, melt and refining procedures can be applied for the axial element recladding, where the fresh fuel and discharged fuel may be added to the fuel in the recycled elements (Hoang et al., 2018).

- Modified CANDLE burnup

Since recladding removes the fuel meat from the cladding, the radiation protection problem becomes more difficult and the facility becomes more expensive and complex. This problem can be solved by the modified CANDLE burnup method (Zaki and Sekimoto, 2012), which can be performed with the fuel meat confined in the cladding.

The CANDLE reactor discharge burnup B must be selected to satisfy $B_2 \leq B \leq B_4$ in Fig. 2A. If we try to use uranium effectively, B_4 is preferred. However, the maximum permissible burnup for the material is very low. At present, in order to avoid the recladding, we must choose a low burnup, usually B_2 . This is the principle of the modified CANDLE burnup.

The fuel pin of modified CANDLE burnup is divided into many axially stacked fuel elements, and each element is covered with cladding material. At the outer boundary of the discharged fuel element ($B = B_2$), the neutron flux level is still high. Therefore, it is better to put the fresh fuel element adjacent to the discharged fuel element for increasing neutron economy. A typical modified CANDLE burnup scheme is shown in Fig. 6. Considering the axial temperature distribution, it may be better to turn it upside down. The obtained discharge burnup for a typical modified CANDLE reactor is about 26% (Zaki and Sekimoto, 2012).

At present, the achievable peak burnup value is not clear. At EBR-II, X425 lead test with U-Pu-Zr ternary fuel had achieved 19.3% burnup and the X435 Mk-III driver qualification test had achieved 19.9% burnup when the EBR-II was shut down permanently in 1994. There was no indication these tests needed to be terminated. Much higher burnup levels might well have been achieved if irradiation had been allowed to continue (Till and Chang, 2011).

Power density flattening and core height shortening

To enhance the economic performance, power density flattening is important. Especially coolant core-outlet temperature flattening is very important. It is also important to shorten the core height, since it increases the power density and reduces the coolant pressure drop in the core. The power density flattening usually increases the criticality, since core surface-to-volume ratio becomes smaller.

Fig. 6 Fuel element shuffling scheme for modified CANDLE.

- MOTTO cycle for core height shortening

The axial location of the burning region moves more rapidly for the higher power density. The power density at the radially central position is higher than at the peripheral position. If there is no neutron diffusion coupling between these positions, the burning region at the central position moves faster than at the peripheral position. However, the neutron diffusion coupling between these positions is considerable, and the burning regions at both positions move at the same speed but the one at the central position stays at a preceding location than at the peripheral position as shown in Fig. 7A for a typical CANDLE burning in a uniform core. This makes it necessary to increase the core height for covering whole burning region. In order to make the axial power peak position radially flat and to reduce the core height, we introduce the multichannel once-through-then-out (MOTTO) cycle (Sekimoto and Nagata, 2010; Sekimoto, 2010a). Detailed procedures for this method are given below:

For each radial position r , the axial center position of power density (centroid position) is defined as:

$$z_c(r) \equiv \frac{\int_{core-bottom}^{core-top} zP(r, z)dz}{\int_{core-bottom}^{core-top} P(r, z)dz} \quad (27)$$

where $P(r, z)$ is the power density at the position (r, z) . At BOC, the centroid surface made by connecting the centroid positions is made horizontal ($z_c(r) = \text{constant}$) as shown in Fig. 7B by adjusting the amount of spent fuel taken out from the top of each radial position. The amount of fresh fuel added to the bottom is the same as the amount of spent fuel removed at the same fuel channel. The burning region shifts downward with the progress of burning ($z_c(0) < z_c(r_1) < z_c(r_2)$ for $0 < r_1 < r_2$). Therefore, at EOC, the centroid surface is not level as shown in Fig. 7C: it is lower in the central region than the periphery. This surface is again made level as shown in Fig. 7B by adjusting the amount of discharged spent fuel and charged fresh fuel at each radial position.

- Thorium added in the inner fresh fuel core region for power density flattening

In order to flatten the radial power distribution, an amount of thorium is added to the fresh uranium fuel uniformly in the inner core region (Sekimoto, 2010a; Okawa et al., 2012). For only uranium fresh fuel (original CANDLE), as already mentioned, the neutron flux has a peak on the core axis and neutrons flow from the core axial region to the periphery. If thorium is added to the inner part of the fresh fuel region, the flux peak will decrease since the η value of ^{233}U produced from thorium is less than that of ^{239}Pu produced from ^{238}U . The thorium addition rates in the fresh fuel inner core region, where thorium-to-uranium ratio is constant over this region, and the boundary position between the inner and outer core regions are adjusted to flatten the radial power density distribution in the inner core. The uranium density in the outer core can be simultaneously adjusted to make the power density distribution continuous at the boundary. Core criticality should be maintained during these processes. In this way, the radial power density distribution in the inner core can be flattened.

Fig. 8 shows the obtained power density distributions for sodium-cooled and ^{208}Pb -cooled fast reactors with metallic fuel (Sekimoto, 2010a); this figure also shows those for the original cores for comparison. The number density ratio of thorium to uranium is 22:78 for sodium cooling core and 37:63 for ^{208}Pb cooling core. The thickness of the outer core is 120 cm for sodium cooling core and 60 cm for ^{208}Pb cooling core. From this, the radial power peaking factor for ^{208}Pb cooling core is 1.063 very close to unity.

How CANDLE reactors satisfy the requirements for future ideal nuclear energy system

Section “A future ideal nuclear energy system” describes the problems imposed on nuclear energy. This section describes how the CANDLE reactor solves these problems (Sekimoto, 2010b).

Resource

The average burnup of spent fuel is about 40% (400 MWd/tHM); in other words, 40% of natural uranium burns up without enrichment or reprocessing.

The present once-through fuel cycle of 4% enriched uranium in LWRs burns up about 5% of the inserted fuel. When tail (depleted uranium) enrichment is 0.1%, the amount of the product (4% enriched uranium) is 16% of the feed natural uranium. The burnup of 5% of this product means the utilization of 0.8% ($=0.16 \times 0.05$) of original natural uranium. Remaining 84% of the original natural uranium is the depleted uranium. If this depleted uranium is utilized as fuel for a CANDLE reactor, where the average discharge burnup is about 40%, about 34% ($=0.84 \times 0.4$) of the original natural uranium will be utilized. Therefore, if an LWR has already generated X Joules of energy, a CANDLE reactor can produce about $42.5(=34/0.8)X$ Joules from the depleted uranium stored at an enrichment facility for LWR fuel.

The following scenario is conceivable. If LWRs produce energy for 50 years and the nuclear energy production rate does not change in the future, we can produce energy for more than 2000 years by using CANDLE reactors with the depleted uranium. Thus, it is not necessary to mine any more uranium ore, and reprocessing facilities are not required.

Nuclear proliferation and physical protection

The enrichment and reprocessing are the most important technologies for the production of atomic bombs. CANDLE reactor can be operated without enrichment or reprocessing forever, once it starts, if only natural or depleted uranium is available. Therefore, CANDLE reactor shows excellent features on both non-proliferation and physical protection.

Safety

The best way for increasing safety features of nuclear reactor is considered to reduce both frequency of undesired events and consequence of severe accidents.

The frequency of undesired events for CANDLE reactor is reduced by many ways as follows. Firstly, the excess burnup reactivity becomes zero, and the shim control rods are not required for CANDLE burning. Therefore, the reactor becomes free from reactivity-induced accidents at operating condition. Secondly, the number density distribution of each nuclide does not change due to fuel burnup. Therefore, the reactor characteristics such as power peaking and power coefficient of reactivity do not change due to burnup. Therefore, the estimation of core condition becomes very reliable. The reactor operation strategy remains unchanged for different burnup stage. Thirdly, since the radial power profile does not change due to burnup, the required flow distribution rate for each coolant channel does not change. Therefore, the orifice control for each channel due to fuel burnup is not required. The operational mistakes are avoided.

The most severe accident of fast reactors is considered CDA. The consequences and possibility of re-criticality accidents at CDA is considerably reduced for CANDLE reactors, since the control rods are not inserted in the core under operating condition, and coolant amount in the core is small.

Reprocessing also has severe problems with regard to the safety of ordinary fast reactors. The CANDLE reactor does not require reprocessing, so there is no such problem.

Waste

The present LWR performs the average discharge burnup of about 5% of the inserted fuel of 4% enriched uranium. On the other hand the average burnup of the spent fuel for CANDLE reactor is about 40%. It is eight times as high as for LWR. Therefore, the spent fuel amount per produced energy is reduced to be one-eighth of once-through cycle LWR.

Reprocessing of discharged fuel and vitrification may reduce the volume of high level wastes, but the total volume of radioactive wastes increases. The once-through fuel cycle system of CANDLE reactor reduces the total volume of radioactive wastes.

The amount of actinides is decreased since they are stored in the core much longer than conventional reactors and fissioned in a considerable amount during this period.

We can use the depleted uranium. The wastes from uranium mining do not appear.

Economy

The cost of nuclear reactor consists of capital, fuel, and O&M (operation and maintenance).

We can expect low O&M cost, since CANDLE reactor is simple.

We can also expect low fuel cycle cost, since the fresh fuel is only depleted uranium or natural uranium, and the reprocessing of discharged fuel is not required.

However, since coolant channel space is smaller than conventional reactors, the core cooling performance is poor. It may result in lower average power density. The low average power density deteriorates strongly its economic performance. Nevertheless, this deterioration can be significantly mitigated by the blanket-less design, no space for control absorbers, short core height and radially flat power distribution (see section **"Power density flattening and core height shortening"**).

Glossary

BOEC/EOEC Beginning/End Of Equilibrium Cycle.

Breeding Converting a fertile isotope into a fissile one by capturing a neutron. Usually the fertile isotope ^{238}U to the fissile isotope ^{239}Pu . Also the fertile isotope ^{232}Th (natural thorium) to the fissile isotope ^{233}U (Shusterman, 2021).

Burnup A measure of the amount of fission energy released from a given quantity of fuel. One unit used for such a measure is FIMA = Fraction (usually given in %) of Initial Heavy Metal Atoms that has fissioned. A more wide-spread unit is MWd kg^{-1} ($= \text{GWd ton}^{-1}$) that measures the amount of thermal energy released from unit weight of the initially loaded HM.

Cladding The structural material that separates the nuclear fuel from the coolant. In fast reactors it is usually made of steel. In light water reactors it is usually made of an alloy of Zirconium (Porter, 2021).

Conversion Ratio (CR) $[\text{amount of TRU in the discharged fuel} - (\text{amount of TRU loaded into core} - \text{amount of TRU fissioned})] / [\text{amount of TRU fissioned}]$. Quantities are for equilibrium cycle.

Neutron Flux Number of neutrons crossing a unit area per second. Reaction rates, such as the fission rate, are proportional to the neutron flux.

Neutron Flux Spectrum The neutron flux energy dependence; i.e., the neutron flux distribution as a function of the neutron energy. Also referred to as the Neutron Spectrum.

Neutron Leakage Probability Fraction of fission-born neutrons that leak-out from the core or from a specific region of the core (such as from the Seed).

Passive Safety (also referred to as Inherent Safety) (Rempe, 2021) A reactor designed in such a way that it mitigates the effects of any mal-function by its inherent design characteristics and can eliminate fuel damage without intervention. The inherent safety features are provided by the laws of physics.

Radiation damage A measure of degradation in the mechanical properties of a structural material (or fuel) induced primarily by high energy neutrons that can displace (knock out) atoms from their original lattice location.

Reactivity and Reactivity Feedback “Reactivity” is a term used to denote the extent of the deviation in the core effective multiplication factor (usually denoted as k_{eff}) from its value at a just critical state (at which state $k_{\text{eff}} = 1.0$). A positive reactivity feedback implies that the ratio of the rate of neutron production to the rate of neutron losses (k_{eff}) is increasing due to a change in a performance characteristic such as temperature or density. One of the necessary characteristics for a reactor to be inherently safe is that the combined effects of all possible changes in reactor conditions due to a power increase will result in a negative reactivity feedback (Tsvetkov, 2021).

SFR Sodium-cooled Fast Reactor (Heidet, 2021).

TRU/HM ratio Ratio of nuclei of all fuel isotopes pertaining to elements heavier than uranium (TRansUranium or TRU) to all fuel isotopes including uranium in addition to TRU.

Introduction

Breed-and-Burn (B&B) reactors have been proposed in the past (Qvist, 2020) as an alternative mode of operation of fast breeder reactors and TerraPower™ is presently pursuing the development of commercial B&B reactors (Gilleland et al., 2008; Hejzlar, 2021). Whereas conventional fast reactors are to be fed with relatively high fissile concentration fuel and their discharged fuel is to be reprocessed and recycled (Heidet, 2021), B&B cores are to be fed with depleted or natural uranium, breed plutonium, and then fission a significant fraction of the bred plutonium in situ. It is expected that B&B reactors will improve the economics of fast reactors relative to that of conventional fast reactors (Heidet, 2021) as they require no enriched fuel (except for the initial fuel loading that will establish the chain reaction) and no fuel reprocessing and recycling. However, in order to sustain the B&B mode of operation, it is necessary to fission at least ~20% of the depleted uranium feed (Petroski et al., 2010; Heidet and Greenspan, 2012; Qvist, 2020); that is, the fuel has to reach an average burnup of approximately 20% FIMA (Fissions per Initial Metal Atom). This corresponds to a peak discharge burnup of about 30% FIMA. The corresponding peak radiation damage of the fuel cladding material will be in the vicinity of 500 DPA (Displacements Per Atom). The maximum neutron induced radiation damage that structural materials had been exposed to so far is approximately 200 DPA (Qvist, 2021). Hence, an extensive R&D effort is required to develop and certify a cladding material that can retain the fuel integrity up to approximately 500 DPA. Such a program will have to include irradiation experiments in fast spectrum together with post-irradiation analysis and may take a long time and be expensive. If thorium is to be used as fertile feed rather than depleted uranium, it is practically impossible to design a critical core with sustainable B&B mode of operation (Petroski et al., 2010; Heidet and Greenspan, 2012). Several concepts of cores for B&B reactors are described in this encyclopedia by Hejzlar (2021), Krepel and Kramer (2021), Qvist (2021), and Sekimoto (2021). The fuel of the molten chloride B&B core described by Krepel and Kramer (2021) is in a liquid state and is not subjected to the same radiation damage constraint as do the solid fuel B&B cores.

The Seed-and-Blanket (S&B) core concept was recently proposed (Greenspan, 2012) to enable to start benefiting from the B&B mode of operation without having to wait for the development of a cladding material that can be licensed for operation at radiation damage levels exceeding 200 DPA. The objective of this Chapter is to describe the S&B core concept and to summarize its attainable performance characteristics as predicted by computer simulations; no such core has ever been built. Selected characteristics of a couple of S&B core designs are compared against those of a conventional Sodium-cooled Fast Reactor (SFR).

The Seed-and-Blanket core concept

Typical Sodium-cooled Fast Reactor (SFR) cores, such as cores for the Advanced Burner Reactor (ABR) and Advanced Recycling Reactor (ARR) (Dubberley et al., 2000; Hoffman et al., 2006; Kim et al., 2009; Heidet, 2021), are designed to have a pancake shape—their height-to-diameter ratio is significantly smaller than 1.0 (Fig. 1A) with the height being typically in the vicinity of 1 m. Such cores feature relatively large probability for neutrons to leak out—typically, on the order of 20% of the fission-born neutrons leak out, mostly in the axial direction. The large neutron leakage probability enables designing the SFR to feature passive (also referred to as

Fig. 1 (A) Highly simplified schematic layout of a conventional Advanced Burner Reactor (ABR) core. There is no blanket fuel in such cores. (B) Highly simplified schematic vertical view of an SFR core with axial depleted uranium blankets (in green). Such cores are typically designed to be breeders; that is, to make fissile fuel at a rate that is equal or larger than the rate of fissile fuel consumption.

inherent) safety by reducing the core positive reactivity feedback to coolant density reduction (causing an increase in the neutron average energy = “spectrum hardening”) and increasing the negative reactivity feedback due to the core radial expansion and fuel axial expansion resulting from increase in core coolant temperature. Passive safety requires that the net reactivity effect of all changes in the core that are induced by core power increase is negative. Besides the safety reason, there is no beneficial use of these leaking neutrons except in cores that are designed to be breeders that feature axial depleted uranium blankets as illustrated in Fig. 1B. In such cores a fraction of the neutrons that leak out from the core are captured in the blanket in the fertile isotope ^{238}U and convert it to plutonium (Pu) thus contributing to the core breeding. But in order to benefit from the blanket, the blanket fuel has to be reprocessed and the Trans-Uranium (TRU), or only Pu, need be recycled back to the core.

The S&B concept, on the other hand, features lower neutron leakage probability from the core—as low as few percent, and achieves passive safety by a unique synergism between the seed and the blanket to be elaborated below. Although many combinations of seed and blanket geometry and composition are possible, we’ll focus on one of the most promising combinations identified: The specific S&B cores addressed consist of a low Conversion Ratio (CR) seed that is fueled with TRU extracted from Light Water Reactor (LWR) Used Nuclear Fuel (UNF) and a thorium-fueled B&B blanket. The primary objective of the seed is to transmute, that is, incinerate the TRU elements that are of proliferation concern, health hazard and expensive to store. The excess neutrons that are generated in the seed from the fission of the TRU nuclei are used to “drive” the sub-critical blanket that radially surrounds the seed, also referred to as the “driver,” as schematically illustrated in Fig. 2A. Whereas the seed fuel is recycled as in a conventional ABR, the blanket operates on a once-through fuel cycle as in B&B reactors; there is no need to enrich the blanket fuel feed and to reprocess and recycle the used blanket fuel. As a result, the fuel cycle cost of the blanket is a very small fraction of that of the seed. A design objective of the S&B core is, therefore, to maximize the fraction of core power that is generated by the blanket. This objective is best obtained by designing the seed to be of an elongated annular shape that features large radial and small axial neutron leakage probabilities that is radially surrounded by thorium blankets, as schematically illustrated in Fig. 2B.

Upper-bound performance—An illustration

The leftmost column of Table 1 summarizes selected design and performance characteristics of a S&B core, denoted as S&B-1, designed to give the maximum power fraction from its thorium blanket, in comparison with those of a conventional ABR core (Hoffman et al., 2006). All the performance characteristics presented in the table pertain to the equilibrium fuel cycle; that is, to cores in which the fuel had been recycled a number of times so that the core composition at the beginning (end) of a given irradiation cycle equals to that of the following cycle. The upper-bound S&B core design referred to in Table 1 significantly deviates from design practices followed by the SFR community in several aspects: (1) The core height and pressure drop are more than twice the commonly used values. This height is typical, though, to that envisioned for B&B cores (Hejzlar et al., 2013). The sensitivity of the S&B core performance to these two design variables will be addressed in the following section. (2) The seed fuel conversion ratio (CR) is zero; its attainment requires use of TRU fuel without a fertile fuel (usually depleted U) component (TRU/HM = 0.995). Such fuels are referred to as fertile-free fuels or inert-matrix fuels. There is no experience in irradiating such a fuel in SFR to the desired

Fig. 2 (A) Schematic layout of a simplified Seed-and-Blanket core. (B) A horizontal cut through a highly simplified S&B core that features an annular seed. More than 40% of the Seed fission-born neutrons leak out in the radial direction. These leaking neutrons drive the subcritical blanket that operates in the B&B mode to generate up to ~ 50% of the core power.

Table 1 Comparison of selected design and performance characteristics of S&B and ABR (Hoffman et al., 2006) cores.

Property	S&B-1	S&B-2	ABR

burnup levels. For comparison, typical fuels for ABR cores feature a TRU-to-HM ratio that does not exceed ~40%; they are designed to have a CR of 0.5–0.75 (Kim et al., 2009).

The fuel of both reactors is in a metallic form and the HM is alloyed with 10 wt% Zirconium that improves the fuel performance under irradiation (Porter, 2021). The fuel rods of the S&B cores examined do not have a fission gas plenum above the fuel section, as do the fuel rods of the ABR and all conventionally designed SFR cores (Heidet, 2021). The function of the fission gas plenum is to accumulate the fission products that are gaseous in the fuel operating conditions without building too high pressure inside the fuel cladding. In typical SFR designs, the length of the fission gas plenum is comparable to the active fuel length so that it almost doubles the coolant pressure drop in the core. In the S&B cores it is assumed that the gaseous fission products are vented from the top of the fuel rod to the coolant from which they get into the inert gas volume that is located above the sodium at the top of the reactor vessel.

These gaseous fission products are then extracted by circulating the inert gas through filters. An illustration of a gaseous fission products venting system concept that allows the fission product gas to get out from the fuel rod and prevents the coolant to get into the rod can be found in [Qvist et al. \(2015\)](#).

The upper-bound S&B (S&B-1) core ([Zhang et al., 2017](#)) has only 30 fuel assemblies in the annular seed that surround 96 fuel assemblies in the inner blanket and are surrounded by 145 fuel assemblies of the outer blanket. Each fuel assembly is of a hexagonal shape of identical outer dimensions and contains 271 fuel rods arranged in a hexagonal lattice as common in SFR core designs ([Heidet, 2021](#)). The seed and blanket fuel rod diameter and spacing between the fuel rods are optimized to meet thermal-hydraulic constraints ([Qvist and Greenspan, 2014](#); [Zhang et al., 2017](#)) while offering the following design objectives: (1) maximum fraction of fission neutrons born in the seed leak out in the radial direction and (2) providing a critical core throughout the cycle. With 47% of the fission neutrons born in the seed leaking out to the thorium blankets, the blanket generates 57.7% of the core total power!

This extremely high leakage probability from the seed to the blanket is a result of using (1) the maximum possible TRU concentration in the seed fuel—enabling to maximize the fraction of fission-born neutrons to be excess neutrons; that is neutrons not required for maintaining the fission chain reaction; (2) the very small annular seed width of only ~ 16 cm, combined with the relatively large seed fuel lattice Pitch-to-Diameter (P/D) ratio¹ that enable most of the excess neutrons to leak from the seed to the inner and outer blankets. In practice, the seed is not a perfect annulus because it has to be made out of hexagonal fuel assemblies of the same dimensions as the blanket fuel assemblies. The width of the S&B core fuel assembly is 16.1 cm—on the order of 2 mean-free-paths (mfp) for fission neutrons collision. The mfp is the distance a neutron will travel, on average, from the location of its emission to its collision with one of the seed constituents. A fission-born neutron has to undergo, on average, many collisions before it is absorbed.

The following subsections discuss unique selected performance characteristics of the S&B-1 core and compares some of which with those of the reference ABR core. A comparison of an easier to implement S&B core, to be denoted as S&B-2, with the S&B-1 core and with the ABR core is provided in the following section.

Small TRU fuel inventory

The TRU containing Heavy Metal (HM) inventory of the S&B-1 core is 4.2 tons versus 9.4 tons of the ABR core. Normalized by the rated thermal power—3000 MWth for the S&B-1 versus 1000 MWth for the ABR cores, the respective values are 1.4 tons per GWth versus 9.4 tons per GWth. Moreover, whereas in the S&B-1 core the TRU is contained in 30 fuel assemblies, in the ABR core all the 144 fuel assemblies contain TRU. However, the ratio of the total length of fuel slugs² that need be fabricated is $(30 \times 2.5 / (144 \times 1.016)) = 0.51$. Normalized by the rated power this ratio becomes 0.17. As the fabrication and handling of TRU containing fuel is very expensive relative to the fabrication and handling of thorium or depleted uranium or natural uranium, the cost of fuel for the S&B-1 core is expected to be smaller than for the ABR.

Ultra long cycles

After reaching equilibrium composition, the S&B-1 core operates in cycles each of which lasts the equivalent of 1550 days at full power (Effective Full Power Days—EFPD). This is a factor of 7 longer than the 221 EFPD of the ABR. At the end of each cycle half of the seed fuel assemblies are replaced by new fuel assemblies; the new assemblies are made of the TRU extracted from the used seed assemblies that are being reprocessed supplemented by TRU extracted from LWR UNF. The innermost 48 blanket fuel assemblies (a blanket fuel “batch”) are removed from the core for cooling and storage; the following 48 fuel assemblies are shuffled to the innermost locations and their locations are being loaded with the innermost 48 fuel assemblies of the outer blanket. Likewise, the remaining fuel assemblies of the outer blanket are shuffled one batch inward and fresh thorium fuel assemblies are loaded into the outermost blanket locations.

In the ABR core, on the other hand, the core is divided into three radial composition zones: the inner zone has the lowest, whereas the outer zone has the highest TRU/HM ratio. This enrichment zoning flattens the radial power density distribution across the core thus enabling to maximize the core average power density and this way to minimize the core volume required for generating the rated power of 1000 MWth. What limits the ABR cycle length to 221 EFPD is, primarily, the so called “burnup reactivity swing”—the change, usually drop, in the core reactivity due to the change in the fuel composition—depletion of fissile fuel and buildup of fission products inventory. Safety considerations restrict this change to approximately 3.5% drop in the core effective multiplication factor ($\Delta k_{\text{eff}}/k_{\text{eff}}$). In the ABR core that features a CR of 0.5, k_{eff} drops with burnup pretty steeply dictating a short cycle duration and 6–7 refueling batches. At the end of each cycle, 1/6th of the fuel assemblies in the inner and central core zones and 1/7th of the fuel assemblies of the outer core zone are removed from the core (for cooling followed by reprocessing) and fresh fuel assemblies are loaded instead. It is apparent that the design of the seed of the S&B-1 core and its fuel management is much simpler than those of the ABR core; both offering a comparable TRU transmutation capability.

The remarkable difference in the cycle length of the two cores being examined is one outcome of the unique synergism between the seed and the blanket. Even though the reactivity ($\Delta k/k$) of the seed drops with burnup steeper than that of the ABR core (because

¹P/D = Pitch/Diameter. The Pitch is the distance between the center of neighboring fuel rods while the Diameter is the fuel rod cladding outer diameter.

²The fuel rod is made of few cm long cylindrical fuel slugs inserted into a steel tube (“the cladding”) and supported from the top by a spring ([Young, 2020](#); [Abram, 2021](#)).

its CR is smaller than that of the ABR core: 0 versus 0.5), the reactivity of the thorium blanket keeps increasing with burnup due to the conversion of thorium to the fissile isotope ^{233}U so that the total change in the S&B-1 core reactivity is much flatter with burnup than that of the ABR core. The longer cycles will enable to operate the S&B cores with a higher capacity factor that is expected to reduce the operation-and-maintenance cost component of the generated electricity.

It is possible to design ABR cores to have longer cycles; the minimum desirable cycle length is 1 year; but this requires to increase the ABR core CR from 0.5 to 0.6 or higher. A higher CR implies a lower transmutation rate per unit power generated implying a smaller specific transmutation capacity.

Very small reprocessing capacity

Even though the rate of TRU transmutation is nearly the same in the two cores compared, the required fuel reprocessing capacity per unit energy generated by the S&B-1 core is smaller than 1/5th that for the ABR core! This remarkable reduction in the required reprocessing capacity will significantly reduce the S&B reactor fuel cycle cost and reduce the investment in the infrastructure required for supporting a fleet of SFRs (Zhang et al., 2018a).

Another useful measure of the required reprocessing capacity is the specific reprocessing capacity—Kilograms of TRU containing fuel that need be reprocessed per Kilogram of TRU transmuted (a primary objective of the ABR and of the seed). The specific reprocessing capacity of the S&B-1 core is nearly 1/5th that of the reference ABR.

What makes the reprocessing capacity per energy generated by the S&B-1 core so much lower is a combination of higher seed discharge burnup—312 MWd kg^{-1} versus 132 MWd kg^{-1} for the ABR, and the large contribution of the blanket—57.7%, to the core power. The seed fuel can reach such a high burnup without exceeding the presently acceptable radiation damage constraint due, primarily, to its very high fissile (and TRU) content that implies a lower flux amplitude for a given specific power—fission power per given HM mass. The radiation damage rate is proportional to the neutron flux amplitude but also depends on the neutron spectrum—the softer the spectrum, the lower is the radiation-damage rate. The neutron spectrum in the seed is softer than in the ABR core due, primarily, to the larger coolant volume fraction (larger fuel rod pitch-to-diameter (P/D) ratio) and high leakage probability of fission neutrons from the seed.

Use of inert-matrix transmutation fuel

The S&B seed fuel is free of fertile fuel; it is an “inert-matrix fuel.” Such fuels are usually considered for so called “source-driven” subcritical reactors designed for transmutation of the LWR TRU (or Pu) waste (Wigeland et al., 2014). Two types of non-fission neutron sources are being considered for such reactors: (1) Spallation neutrons that are to be generated by impinging high energy ions onto a high atomic number target such as lead or tungsten. High energy particle accelerators are required for generating the needed current of high energy ions. Such reactors are also referred to as “Accelerator-Driven Systems” or ADS (Brown et al., 2016). (2) Fusion neutrons that are to be generated by fusion devices having low “energy gain.” Such reactors, also referred to as “Fusion-Fission Hybrid Reactors,” are being considered as possible early application of the fusion technology (Stacey, 2020). Inert matrix fuel is usually considered inadequate for use in critical reactors not only because of the steep drop in the core reactivity with burnup but also because of safety concerns—such reactors tend to have a positive Doppler coefficient—an increase in reactivity as a result of an increase in the fuel temperature—unacceptable from safety considerations. In the S&B core designs reported in Table 1 the Doppler coefficient is almost as negative as in the reference ABR core that does not use inert matrix fuel. This is attributed to the large amount of thorium (fertile fuel) in the blanket that is tightly neutronicly coupled with the seed fuel, combined with the relatively high power generated by the blanket batches adjacent to the seed. One of the unique features of the S&B core concept is that it enables to use fertile-free fuel without an external neutron source. The S&B approach to use of inert-matrix fuel is likely to be significantly simpler and less expensive than use of spallation or fusion neutrons driven sub-critical reactors.

Small positive sodium reactivity feedback enabling inherently safe design

As mentioned above, conventional SFR cores are usually designed to have a high neutron leakage probability in order to reduce their positive reactivity feedback to coolant voiding below a level that enables their design to be inherently safe. Although the S&B-1 core features much lower net leakage probability than the ABR core, its positive reactivity feedback to coolant voiding is comparable, or even slightly smaller, than that of the small volume high-leakage ABR core (Table 1). This is attributed to a combination of three features: (1) the large neutron leakage probability from the annular seed to the blanket (47.7%) and its increase with seed coolant voiding (to 47.9%); (2) the neutron that leaks from the TRU seed to the thorium blanket becomes less “important”—its probability to contribute to the chain reaction diminishes; (3) the unique physics characteristics of the thorium fuel: (a) the number of fission neutrons generated per neutron absorbed in ^{233}U (the so called “ η ” value) increases with the energy of the neutron that causes fission much slower than in ^{239}Pu ; (b) the threshold for fission of ^{232}Th is at higher neutron energy than that of ^{238}U and the ^{232}Th fission probability increase with neutron energy is significantly smaller. As a result of “a” and “b,” voiding a thorium blanket results in a significantly smaller positive reactivity insertion than voiding a blanket fueled with depleted uranium.

Thorium utilization

The S&B core concept enables significant thorium resource utilization in a critical fission reactor without a need for thorium reprocessing technology. In the metallic thorium fueled S&B-1 core, approximately 7% of the fed thorium is fissioned without recycling. This thorium utilization is about 12 times the natural uranium utilization in LWRs. This high thorium utilization is possible due to the beneficial use of the excess neutrons from the seed that drive the blanket in a subcritical breed-and-burn mode. Significantly higher thorium utilization can be achieved by softening of the neutron spectrum in the blanket and/or by the development of a cladding material capable of withstanding a higher radiation damage (Zhang et al., 2018b).

More conservative S&B core design

The performance characteristics of the S&B-1 core set an upper bound on the fraction of the core power that can be generated by the thorium B&B blanket and on the cycle length that could be provided by the S&B core concept. The present section quantifies implications on the S&B core performance resulting from more conservative design practices that result in the S&B-2 design reported in the 2nd column of Table 1. The specific design examined features a core height of 120 cm instead of 250 cm, a pressure drop of 0.3 MPa rather than 0.9 MPa. Its power level was down-rated to 2000 MWth to meet thermal-hydraulic design constraints. The S&B-2 seed fuel uses TRU alloyed with 40 instead of 10 wt% Zirconium. TRU-40Zr is assumed for the seed fuel because it is supported by irradiation experiments (Hayes et al., 2015; Zhang et al., 2018b). The outer dimensions of the S&B-2 core are comparable to those of the S-PRISM core that is being offered by GE (Dubberley et al., 2000) and could fit within the S-PRISM reactor vessel.

Relative to the S&B-1 design, the S&B-2 design requires more than twice fuel assemblies for the seed and correspondingly reduced number of inner blanket seed assemblies. The axial neutron leakage probability from this core is three times higher than from the S&B-1 core. As a result of these changes, the fraction of excess seed neutrons that is available for driving the blanket is lower and, correspondingly, the fraction of core power that is generated by the blanket is lower—only 43.1%. The S&B-2 core reactivity swing is significantly higher than that of the S&B-1 core and this forces to shorten its fuel cycle to only 525 EFPD—which is still more than twice that of the reference ABR core. However, the TRU inventory of the S&B-2 core is significantly lower than that of the S&B-1 core—2.5 versus 4.2 tons, and its burnup can be noticeably higher for the same radiation damage. As a result, the reprocessing capacity as well as the specific reprocessing capacity required for the S&B-2 core are lower—only 349 (kg GWth⁻¹ EFPY⁻¹) and 2.5 (kg reprocessed/kg transmuted) versus 495 and 3.1 for the S&B-1 core. The higher seed discharge burnup as well as higher thorium utilization are due to (1) the somewhat softer neutron spectrum of seeds the fuel of which contains 40 instead of 10 wt% Zirconium, and (2) The increase in the ratio of the axially averaged—to peak power density; that is, to the flatter axial power density distribution in the shorter core; the radiation-damage constraint limits the peak rather than the average power density. The safety related characteristics of the two S&B cores are comparable.

It is concluded that even using more practical design practices the fuel cycle benefits from S&B cores are expected to be significant.

Fuel cycle characteristics

Zhang et al. (2018a) compare the fuel cycle performance of the S&B-1 reactor against the reference ABR and a conventional Pressurized Water Reactor (PWR). The fuel cycle performance is evaluated assuming a 2-stage PWR-SFR energy systems for the fast reactors (SFR: ABR and S&B) and a once-through fuel cycle for the PWRs. In the 2-stage energy system it is assumed that the ratio of the installed capacity of the SFR and PWR is such that the transmutation rate of TRU from the PWR UNF equals the TRU production rate in the PWR. Other study assumptions, including the cost of various fuel cycle activities, can be found in Zhang et al. (2018a).

Fuel cycle cost

Fig. 3 compares the fuel cycle costs of the PWR-ABR, PWR-S&B, and PWR systems. As the fuel reprocessing capacity of the S&B core is only about one-fifth that of the equal power ABR, the fuel cycle cost of the PWR-S&B system is lower than that of the PWR-ABR system; it is even lower than that of present PWRs. There is significant uncertainty in the fuel cycle costs reported in Fig. 3 due to uncertainties in the unit cost assumptions used by Zhang et al. (2018a).

Due to the significantly longer fuel cycle, the capacity factor of the S&B-1 reactor is expected to be about 10% higher than that of the reference ABR. The higher capacity factor is expected to result in lower Operation and Maintenance (O&M) and capital cost components of the S&B reactor cost of electricity (Rothwell, 2021). The capacity factor benefits of the S&B-2 reactor will be significantly smaller due to its shorter cycle length.

Waste characteristics

Fig. 4 compares the specific radioactivity—in Curies (Ci) per unit of electricity generated (in GWe EFPY) of the three energy systems at short-term (10 years) and long-term (100,000 years) after the fuel is discharged from the core.

Fig. 3 Fuel cycle cost of PWR-ABR, PWR-S&B, and PWR.

Fig. 4 Radioactivity of UNF + HLW from PWR-ABR, PWR-S&B, and PWR energy systems at 10 years (A) and 100,000 (B) years after fuel discharge. $1 \text{ Ci} = 3.7 \times 10^{10}$ decays per second.

The higher short-term radioactivity of the Fission Products (FPs) from the PWR (Fig. 4A) is mainly attributed to the lower thermal efficiency compared with that of the fast reactors ($\sim 30\%$ versus $\sim 33\%$). In addition, ^{235}U fissions yield FPs of slightly higher radioactivity than those from ^{239}Pu fissions, but this makes a small difference. The ^{233}U FPs are slightly more radioactive than the ^{235}U FPs making the short-term radioactivity of the S&B reactor waste slightly higher than that of the ABR. The ^{233}U discharged from the S&B thorium blanket has no significant impact on the short-term radioactivity because ^{233}U has a very long half-life of 159,200 years. In the fuel discharged from the PWR the plutonium, primarily ^{241}Pu , contributes notably to the short-term radioactivity.

In the long-term, the discharged ^{233}U is the predominant contributor to the higher radioactivity of S&B relative to the reference PWR and ABR (Fig. 4B). The long-life ^{233}U decays into highly radioactive isotopes including ^{209}Pb , ^{213}Bi , ^{217}At , ^{221}Fr , ^{225}Ra , ^{225}Ac , and ^{229}Th . The discharged plutonium and minor actinides from the PWR-ABR and the PWR systems as well as the S&B seed undergo substantial decay by 100,000 years, and their decay daughters are less radioactive.

Similar conclusions regarding the short-, and long-term ranking were found (Zhang et al., 2018a) for the radiotoxicity of the waste from the three energy systems. The radiotoxicity was evaluated using a couple of measures—the inhalation radiotoxicity and the ingestion radiotoxicity. For details see Zhang et al. (2018a).

Proliferation resistance

The proliferation resistance is evaluated based on the plutonium inventory, fissile plutonium fraction, decay heat and spontaneous fission neutrons emission rate per unit weight of the recovered plutonium, $^{238}\text{Pu}/\text{Pu}$ ratio, and $^{232}\text{U}/^{233}\text{U}$ ratio. ^{238}Pu , ^{240}Pu , and ^{242}Pu have high spontaneous fission rate which can significantly reduce a weapon's yield; ^{238}Pu also has a large decay heat per unit weight that further complicates the design of an explosive device (Pellaud, 2002; Xu et al., 2005).

Due to the higher burnup, the fuel discharged from the S&B-1 seed has the lowest fissile plutonium fraction and the highest $^{238}\text{Pu}/\text{Pu}$ ratio of 6.1%: much higher than that of the ABR (4.1%) and PWR (3.0%). Therefore, the plutonium recovered from the S&B core is the least attractive for making weapons.

The ^{233}U produced in the thorium blanket of the S&B reactor is, in principle, applicable for weapon use because the critical mass of ^{233}U is close to that of ^{239}Pu whereas its spontaneous fission rate is much lower (Kang and Hippel, 2001). Nevertheless, the decay chain of the co-product ^{232}U includes ^{208}Tl which generates highly penetrating 2.6 MeV gamma rays; therefore, a contamination of ^{232}U makes ^{233}U a less desirable weapon material as it is very difficult to separate ^{232}U from ^{233}U due to their close atomic mass. After the in-growth of ^{208}Tl , the dose rate from ^{233}U containing 1 ppm ^{232}U is about the same as that from reactor-grade plutonium (IAEA, 1999; Kang and Hippel, 2001). The thorium fuel discharged from the blanket has a $^{232}\text{U}/^{233}\text{U}$ ratio of 2233 ppm, well above the contamination level that requires remote operations to extract ^{233}U on a large scale without incurring large occupational dose (Forsberg and Hopper, 1998).

Nevertheless, the uranium in the fuel discharged from the S&B core blankets will need to be safeguarded to prevent proliferation, similar to the situation for the PWR reactor-grade plutonium. However, the breed-and-burn thorium blanket has an intrinsic proliferation resistance since the ^{233}U concentration in the discharged fuel is 8%. According to Bathke et al. (2014) dilution with $> 80\%$ ^{238}U or 70% ^{232}Th makes the fissile fuel unattractive to a sub-state actor. Moreover, the fissile uranium (mainly ^{233}U) in the blanket discharged fuel can be diluted with depleted uranium to make it even harder to extract. It is also possible to increase the $^{232}\text{U}/^{233}\text{U}$ ratio in the discharged fuel by softening the spectrum in the blanket (Zhang et al., 2018b). More information regarding proliferation resistance of the nuclear fuel and fuel cycle can be found in Cheng (2021).

Phased development of B&B reactors

The radiation damage constraint assumed for the cladding of all S&B cores examined so far is 200 DPA. Improved structural materials that are capable to withstand a higher radiation dose are under development (Allen et al., 2015). A sensitivity study was conducted to quantify the improvement of the S&B core performance in response to a successful development and certification of structural materials that will enable increasing the radiation damage limit from 200 to 300 or 400 DPA. For this sensitivity analysis, the DPA value of the seed fuel is kept at 200 DPA since the discharge burnup of its fuel (approaching 400 MWd kg^{-1}) is already higher than $\sim 200 \text{ MWd kg}^{-1}$ demonstrated so far (Hayes et al., 2015). The cores examined are 250 cm tall and feature 0.9 MPa pressure drop. The seed fuel is TRU alloyed with 40 wt% Zirconium.

It was found (Zhang et al., 2017) that when the blanket fuel is discharged at a higher DPA value and, hence, higher burnup, the reactivity of the blanket fuel increases. As a result: (1) the blanket can generate a larger fraction of the core power; (2) the cycle length be extended due to a smaller burnup reactivity swing. The positive feedback to coolant voiding also decreases due to a larger thorium blanket power. At 400 DPA, the B&B blanket can generate 64.2% of the core power; the thorium utilization increases to $\sim 17\%$ FIMA—close to 30 times the natural uranium utilization in contemporary LWRs; the reprocessing capacity required to support this S&B core drops to $373.4 \text{ kg GWth}^{-1} \text{ Yr}^{-1}$ which is only 13.5% the $2767.2 \text{ kg GWth}^{-1} \text{ Yr}^{-1}$ capacity required for the reference ABR core.

Alternative fuel cycle options

A couple of alternative options for advanced fuel cycle could be enabled by the S&B core concept; they involve utilization of the fissile fuel accumulated in the thorium blanket.

One option is to recycle the ^{233}U (or all Trans-Thorium elements) bred in the S&B core blanket into PWRs. It was found (Zhang et al., 2018b) possible to reduce the SFR-to-PWR installed capacity ratio required for a sustainable PWR-SFR-PWR energy system from 0.59 for the PWR-S&B system to 0.29 for the PWR-S&B-PWR system. In this 3-stage energy system, the first stage is made of conventional enriched uranium fueled PWRs (BWRs could be used as well), the second stage are S&B reactors featuring TRU-incinerating seed and thorium B&B blanket, while the third stage are PWRs (BWRs) that use the fissile fuel bred in the S&B core blankets.

The other option is to use the fissile fuel extracted from the thorium blanket to feed, and thus enable, new promising fuel-self-sustaining thermal and epithermal nuclear energy systems that operate on the Th- ^{233}U fuel cycle. Examples are heavy-water and molten-salt reactors (Ignatiev, 2021).

For all of the above ^{233}U -based fuel cycle options, the S&B core can be viewed as an enabling device that converts TRU waste into a comparable or even larger amount of ^{233}U resource that is not available in nature.

Technology gaps

The study of the feasibility of the S&B core concept results from which are reported above devoted much of its resources to search for S&B core designs that either minimize the required capacity for fuel recycling per unit of electricity generated or per amount of TRU transmuted, or maximize the blanket fuel discharge burnup without violating the presently acceptable radiation damage and other constraints. Being a concept-feasibility-assessment the study focused on the equilibrium core performance and the analysis was done using a simplified R-Z core model with the fuel batches represented as annuli. Moreover, neither transient/accident analysis nor detailed fuel performance and economic analyses were performed. In addition, the 200 DPA used for the radiation damage constraint is inconsistent with the fast-fluence constraint of $4 \times 10^{23} \text{ n/cm}^2$ in use by Argonne National Laboratory and other fast reactor designers. Hence, technological gaps exist between the present state of knowledge of S&B core design and defendable license-able practical designs of S&B cores. Following is a brief description of these technological gaps.

Realistic core designs

Rather than using R-Z geometry to represent the core, future S&B core analyses should represent the core design assembly-by-assembly and incorporate a right number of control and safety assemblies at discrete locations. An explicit shuffling pattern will have to be used for each fuel assembly so that peak assembly power, peak burnup and peak radiation damage could be accurately determined.

Detailed safety analysis

Detailed safety analysis will have to be performed for selected S&B core designs to assure that these designs are indeed inherently safe and license-able. Whereas the feasibility study performed so far only quantified and compared reactivity coefficients of the different designs, the detailed safety analyses will have to perform time-dependent transient and accident simulations using licensed safety codes.

Approach to equilibrium

A study need be undertaken to identify a promising strategy for transitioning from beginning-of-life (BOL) to equilibrium core composition in the most cost-effective way. Among the approaches to be explored: (1) Enriching the first blanket loading with enriched uranium (or Pu or TRU) trying to match the equilibrium core geometry and power density; (2) Starting with a larger volume lower TRU concentration seed that will enable to safely operate the SFR at full power from day one and gradually build up the ^{233}U concentration and power density in the thorium blanket assemblies.

A comprehensive system analysis

A systematic comprehensive comparison needs to be made between couple of sustainable PWR-SFR energy systems: one using S&B type and the other using conventional ABR type SFRs. The comparison needs to include an estimate of the investment required for the commercialization of these energy systems and an estimate of the relative cost of electricity from the two energy systems when commercial. Also need be compared is the environmental impact of the waste coming out from these energy systems, as well as these systems proliferation resistance.

Fertile-free seed fuel

Acceptable design of TRU-40Zr fuel rods to high burnups is required. In addition to numerical fuel performance analysis, irradiation experiments and post-irradiation analyses will have to be performed to determine the acceptable discharge burnup.

Thorium-base blanket fuel

There is no sufficient experience in the fabrication, irradiation and storage of metallic thorium fuel envisioned for the blanket of the S&B cores. Much more scarce is experience in the fabrication and irradiation of thorium hydride fuel as well as of fuel containing ThN fuel kernels the use of which was found (Zhang et al., 2018b) to offer significant increase in the thorium utilization. As in the case of the seed fuel, there is a need to develop performance prediction capability for thorium-based blanket fuel.

Thorium fuel waste disposal

Large inventories of used nuclear fuel will be accumulated from the breed-and-burn blankets of the S&B cores. There is no commercial experience in storage of thorium-based UNF as well as in the disposal of such fuel. Such technologies need be developed.

Thorium fuel recycling capability

If one wishes to implement one of the applications described in the section “Alternative fuel cycle options” it will be necessary to reprocess the thorium-based blanket fuel. For such applications it will be necessary to develop commercial-scale thorium fuel reprocessing capability as well as reprocessed thorium fuel re-fabrication capability.

Summary

The Seed-and-Blanket core concept presented in this chapter is found highly promising as it enables to benefit from the breed-and-burn mode of operation without exceeding the radiation damage limits structural materials had been successfully exposed to in fast spectrum reactors. The benefits identified include the following:

- Improvement in the economic viability of SFRs due to a significant reduction in the fuel cycle cost and, possibly, an increase in the capacity factor that may be enabled by the longer cycles.

Table 2 Summary of the unique synergism between low CR seed (“driver”) and thorium B&B blanket.

<i>Cause</i>	<i>Effect</i>
Lower CR seed	A. Higher TRU/HM and larger P/D ratio B. Larger fraction (>40%) of fission neutrons leaking from the seed to the blanket C. Larger fraction of core power generated by the blanket D. Lower fast neutron flux in the seed and higher discharge burnup of the seed fuel for radiation damage of 200 DPA E. Lower fuel reprocessing and remote fabrication capacity
Thorium breed-and-burn blanket	A. No thorium reprocessing technology required B. Large reactivity gain in the blanket with burnup which significantly compensates for the reactivity loss in the seed → longer cycles and higher capacity factor C. Small positive feedback to coolant voiding—comparable or smaller than that of high leakage ABR cores D. Negative Doppler reactivity coefficient even when non-fertile fuel is charged to the seed E. Application of non-fertile fuel for the seed without a need for a spallation or fusion neutron sources F. Significant thorium resource utilization without exceeding the proven radiation damage constraint G. In case blanket fuel is reprocessed → Very effective conversion of TRU waste into ^{233}U fissile resource thus enabling new fuel-self-sustaining thorium-based energy systems
Larger internal blanket	A. Larger leakage from seed and higher fraction of the core power generated by the blanket B. Smaller burnup reactivity swing per year C. Smaller void reactivity worth D. Longer cycles; higher capacity factor E. Smaller radial power peaking factor

- Significantly smaller investment in the construction of the fuel reprocessing and recycled fuel fabrication infrastructure required to support a given capacity of SFRs and more economical transmutation of light-water reactor (LWR) TRU.
- Significant utilization of thorium without having to develop thorium fuel reprocessing capability.
- A very efficient conversion of TRU (could be only Pu) to ^{233}U thus enabling deployment of new promising energy systems that use the Th- ^{233}U fuel cycle. These applications will require reprocessing of the thorium blanket fuel.

A more comprehensive comparison between the S&B and ABR core performance is required in order to accurately quantify the claimed benefits being offered by the S&B cores. A more thorough R&D is required before it will be possible to commercialize S&B type SFRs.

The benefits from the S&B core concept outlined in this chapter are due to the unique synergism that exist between a TRU (or Pu) incinerating seed (driver) and a breed-and-burn thorium blanket. This unique synergism is summarized in [Table 2](#).

Acknowledgment

The research summarized in this chapter was performed using funding received primarily from the DOE Office of Nuclear Energy's Nuclear Energy University Programs and, initially, from Terra-Power LLC. It used the Savio computational cluster resource provided by the Berkeley Research Computing program at the University of California, Berkeley.

Introduction

In order to combat climate change and make some strides towards the Paris agreement goals ([United Nations, 2015](#)), the world will need to harness all low carbon energy sources. The specific goal is to “Holding the increase in the global average temperature to well below 2 °C above pre-industrial levels and to pursue efforts to limit the temperature increase to 1.5 °C above pre-industrial levels, recognizing that this would significantly reduce the risks and impacts of climate change.” Nuclear is currently the second largest low carbon source of electricity (after hydro) and deserves due consideration to play its part in a future sustainable energy mix. To support the reduction of greenhouse gases and the further deployment of low carbon but intermittent wind and solar generation, nuclear power – as a dispatchable low carbon source – should surely play a key role. Together with hydropower, nuclear is the only low-carbon source of energy that can replace fossil fuels for 24/7 baseload power.

The potential role of nuclear power was also addressed in the Intergovernmental Panel on Climate Change (IPCC) Special Report on Global Warming of 1.5 °C ([IPCC, 2018](#)) where nuclear need to play a substantial role if the climate targets are to be reached: “Nuclear power increases its share in most 1.5°C pathways with no or limited overshoot by 2050.” In the more recent International Conference on Climate Change and the Role of Nuclear Power ([IAEA, 2020b](#)) the need to include the SMRs to meet climate and sustainable development goals were clearly recognized. “Some Member States may not be able to integrate large nuclear projects in the immediate future, due to existing grid size, lack of domestic demand, or affordability. For these countries, SMRs could be an effective option” ([IAEA, 2020b](#)).

Electricity production from nuclear power first become a reality in 1954 (the AM-1 Obninsk Nuclear Power Plant in the Soviet Union became the first reactor connected to an electrical grid and supplied 5 MW), followed by the first commercial power operation of Calder Hall Nuclear Power Station in the United Kingdom, consisting of four 60 MWe Magnox reactors ([ICTP, 2019](#)). Since

then, hundreds of commercial power plants of various designs and different materials were deployed in countries all around the world. These reactors (and also all other experimental or prototype reactors) are generally classified by their materials, purpose, moderator, coolant, or the neutron energy spectrum. More recently, also the time of construction or the generation of the design has been used to classify the reactors.

Reactors are thus classified by coolant such as Light Water Reactors (PWR or BWR) cooled by normal water, or heavy water moderated and cooled (PHWR). Another example is the molten salt reactor (MSR), where the fissile fuel is dissolved in a molten salt that is also the coolant or heat transfer medium. Final examples include High Temperature Gas-cooled Reactors (HTGR) or fast neutron spectrum reactors cooled by either sodium or a heavy liquid metal like lead or the lead-bismuth eutecticum. Coming to Small Modular Reactors (SMRs), it must be noted that these are newer generation reactors typically rated at 300 MW electric power and having distinct features, as to be defined in the following sections. The SMRs can include any of the reactor types defined above.

There is increasing interest in SMRs and their applications especially from countries with smaller grids and less access to capital to afford large capital projects. SMRs also target the rest of the energy value chain to produce heat or to be used to support industrial processes. This will also be explored in the sections below.

What is a small modular reactor?

SMRs are newer generation reactors designed to generate electric power typically up to 300 MW, whose components and systems can be shop fabricated and then transported as modules to the sites for installation as demand arises. SMRs include both evolutionary designs, which are based on improvements to existing designs by minimizing the technological risk, and innovative designs, that incorporate radical changes in the use of materials, fuel and system configurations. They can also respectively be seen as Generation III+ and Generation-IV designs (Reitsma, 2020).

In general, at the one end of the technology readiness level, the water cooled SMRs are built onto the well-established technology of the large fleet of operating nuclear power plants, while, e.g., the MSRs at the other, are truly innovative with a limited technology base. The fast neutron spectrum and high temperature SMRs are both considered as Generation-IV reactors, but are also built upon the experience obtained in the respective prototype and commercial plants.

SMRs are under development for all principal reactor lines: water cooled reactors (Subki, 2021a), high temperature gas cooled reactors (Fütterer, 2021; Reitsma, 2021) liquid-metal, sodium (Smith, 2021) and gas-cooled reactors with fast neutron spectrum (Hatala, 2021), molten salt reactors (Fratoni, 2021), and most recently microreactors (Wallenius, 2021). The IAEA booklet on Advances in Small Modular Reactor Technology Developments (IAEA, 2020a) provides an excellent and comprehensive summary of the leading SMR designs. Most of these designs are land-based but the deployment can also be a floating nuclear power plant (Subki, 2021b) constructed on a barge.

General design characteristics

As explained above SMRs include a loose family of modern advanced power reactors with lower power output that share certain characteristics. Enhanced safety is the most important feature shared by all SMR designs. This is followed by simplicity and reduced cost to make it more affordable. It represents a nuclear option to meet the need for flexible power generation for a wider range of users and applications.

One of the initial motivations to develop SMRs was to have a smaller nuclear module that could replace aging fossil-fired units while making use of the existing infrastructure. The unit size was therefore similar sized to the older fossil fired units. It also targets cogeneration (electricity and heat) needs in remote and off-grid areas.

As smaller advanced reactors SMRs have enhanced safety margins through inherent and/or passive safety features. These will be discussed in more details later.

SMRs designs introduce simplifications by modularization and system integration. By decreasing the thermal power many systems and components can be integrated or even discarded. For example the use of natural convection will exclude the need for primary pumps.

SMRs are to be deployed as multiple modules. Modules are typically self-sustained and independent but two or more modules could be located in the same location or even same reactor building. These could be controlled from a single control room with one operator overseeing multiple reactors. Although this could reduce staff it requires a new approach for I&C systems.

SMRs also include the extensive use of modularization in construction. Some of these concepts are already being used on large NPP construction but these are typically complex, very heavy and need additional infrastructure to be added on site. For SMRs it means factory manufactured, tested and quality assurance and then transported to site by heavy truck, rail, or barge shipping. This should lead to faster construction and allow the incremental increase of capacity addition as needed.

SMRs promise much smaller sites and that the Emergency Planning Zone can be reduced, possibly to the site boundary. This could mean that SMRs could be located close to population centers and therefore the end users of its electricity and possibly district heating. Similarly, SMRs should be located next to heat users in industrial complexes.

Rationale for introducing SMRs: Deployment and market

Economic considerations and especially increased affordability are an important promise made by SMR developers that make it attractive for many more countries and potential users. The capital needs for large nuclear power stations are beyond the means of most utilities and private companies, even many smaller states. So SMRs are envisioned for niche electricity or energy markets where large reactors would not be viable. SMRs designs are more flexible and attract a wider range of potential users, be it utilities serving a smaller electricity grid, an industry complex that try and decarbonize its process heat sources, or a remote village or mining operation that currently relies on diesel generators to provide electricity at high cost.

Advantages on larger more established electricity grids have also come to the fore. SMRs can contribute to load follow operations, switching between different products and enable larger renewable penetration through hybrid nuclear/renewables energy systems (Hussain et al., 2019). A distributed generation will stabilize the grid network, reduce losses due to long transmission lines and by replacing aging fossil plants existing infrastructure can be used and social impact around these sites minimized (compared to the total closure of fossil plants). Modules can also be added as and when needed preventing price instabilities due to oversupply.

The financing of large nuclear projects is challenging. Through modularization technology, SMRs target the economics of serial production with shorter construction times. For capital incentive projects a shorter project duration and earning revenue from the first units, while constructing later units, can make a huge difference. In factory manufacturing also contribute to lower risks since delays and the assurance of quality standards are much easier in the controlled environment of a factory, compared to a construction site.

Certain families of SMRs such as HTGRs are better suited for partial or dedicated use in non-electrical applications such as providing heat for industrial processes, hydrogen production or sea-water desalination. Process heat or cogeneration results in significantly improved thermal efficiencies leading to a better return on investment. Innovative power conversion cycles with thermal storage enhance the flexibility of SMRs further as short periods of over generation (> 100%) is made possible without impact on safety while benefiting from better utilization of capital.

The marine based deployment on floating platforms brings new markets to SMRs. It opens new business models for ownership or operators, may be more flexible to be sited (many well protected harbors) and has the advantage that it is floating on the ultimate heat sink – the sea. It also has the possibility to be deployed in emergencies for humanitarian assistance to provide electricity, heat and clean water to affected communities.

Safety characteristics of SMRs

All SMRs claim enhanced safety features mostly through the use of passive safety systems and simplifications.

For LWR based SMRs options include:

- the use of natural convection as the primary flow, excluding the primary pumps and related accident scenarios.
- SMRs designs introduce simplifications by modularization and system integration also to enhance safety. For example, an integrated PWR design could include all the primary system components within a single vessel. This eliminates loop piping and external components, thus enabling compact containment and plant size and reduced cost. It further eliminates accident scenarios like a large loss of coolant accident (LOCA) since no large pipes are connecting the primary pumps with the reactor vessel. See Ingersoll (2021) for an illustration of this concept.
- Improved containment options such as passively cooled containment, concrete containment with spray system and pressure suppression containment.
- Severe accidents mitigation features such as in-vessel corium retention and hydrogen passive autocatalytic recombiner.
- Some innovative LWR SMR designs could eliminate many of the safety systems required for large NPPs. The NuScale design is one example that has eliminated many safety systems reducing the number by more than a factor of two. Due to the guard vessels used in a large reactor pool, systems such as containment spray, emergency diesel generators, safety injection system or a residual heat removal system, is no longer necessary.

General safety features include:

- The use of internal (within the vessel) control rod drive mechanisms therefore excluding control rod ejection accidents.
- Residual heat removal system (passive).
- Underground construction for enhanced security and seismic stability. It can also provide protection against external impacts including large aircraft impacts.
- Ability to survive a station blackout.
- The designs have a long grace period where no operator interaction is required, typically between 24 and 72 h, or even longer. This give ample time to evaluate the situation carefully and take any actions that may be needed to bring the reactor to a safe state.

Some of the advanced designs make use of other safety characteristics. In the case of HTR SMRs the use of TRISO coated particle fuel is the main safety feature leading to significantly improved safety, the removal of decay heat by natural means only, i.e. no melt-down. In these designs the early or large release of radionuclides are not seen as a credible event since almost all radioactivity is contained within the coated particle fuel (Reitsma, 2021).

Current status of SMR designs

A major milestone has been reached in SMR technology deployment when the Akademik Lomonosov floating power unit has been connected to the grid and started commercial operation in May 2020. The plant consists of two modules KLT40S and deployed in the Russian Federation. KLT-40S is a compact-PWR to produce 35 MW(e) per module.

Two industrial demonstration SMRs are in an advanced stage of construction. In the People's Republic of China the HTR-PM, a high temperature gas cooled reactor with its two reactor modules is progressing well. Civil construction of HTR-PM in the Shidao Bay site is completed, the two reactor pressure vessels were installed in 2016, and the two steam-generators hoisted in-place in July 2019. It targets initial criticality in 2021 with commercial demonstration to follow.

In Argentina the CAREM reactor, an integral type PWR, is being constructed at the site of Atucha-II NPP. Despite recent project delays due to funding from the government the project is back on track. It is scheduled to start operations in 2023. CAREM-25 is an integral-PWR to produce 27 MW(e), adopting advanced features that include an integral primary cooling system using natural circulation, in-vessel hydraulic control rod drive mechanisms and fully passive safety systems.

A summary of these three forerunners can be seen in **Table 1** with some of its main characteristics highlighted. Many SMR designs make use of slightly higher enrichments predominantly to increase the cycle lengths and overcome higher neutron leakages than in larger reactors.

Table 1 SMRs under construction and their main characteristics.

	KLT-40S	HTR-PM	CAREM
			
Country	Russian Federation	China	Argentina
Reactor type	PWR	Modular pebble bed HTGR	Integral PWR/Natural Circulation
Power MW _{th}	Total 150	2 × 250	100
Electric output MW _e	2 × 35	210	30
Fuel type	UO ₂ pellet in silumin matrix	TRISO Spherical elements with coated particle fuel	UO ₂ pellet/hexagonal
Enrichment %	18.6%	8.5	3.1
Fuel cycle (months)	30–36	Online refueling	24
Distinguishing features	Floating power unit for cogeneration of heat and electricity; no onsite refueling; spent fuel take back	Inherent safety, no need for offsite emergency measures	Core heat removal by natural circulation, pressure suppression containment
Status	Akademik Lomonosov FNPP Connected to the grid in Pevek in December 2019. Entered full commercial operation in May 2020.	Finalizing construction, startup commissioning test of primary circuit in 2020. First operations expected in 2021	Under construction (as prototype). First criticality expected in 2023

Fig. 1 Status of projected deployment timelines for some SMRs as expected in summer 2020. International Atomic Energy Agency (2020a) *Advances in Small Modular Reactor Technology Developments – 2020 Edition*, https://aris.iaea.org/Publications/SMR-Book_2020.pdf.

The deployment of several more SMRs are expected soon. In the Russian Federation it was announced that a construction license has been issued for the BREST-OD-300 reactor. It will be the world's first experimental demonstration power unit featuring a lead-cooled fast neutron reactor (WNN, 2021). The ACP100 small modular reactor at Changjiang in Hainan province, China, has also received a construction license since the preliminary safety analysis report (PSAR) was reviewed and approved at the National Nuclear Safety Administration. Construction of the demonstration unit - also referred to as the Linglong One design can commence (NBN Media, 2020). The NuScale SMR has received US design certification (WNN, 2020) in September 2020 and plan to build at a site at the Idaho National Laboratory. In Fig. 1 a scenario for possible SMR deployment is given taking the design maturity and current licensing status into account. Many of the SMR designs are targeting the 2020's to start construction of their first unit.

There are currently more than seventy (70) SMR designs under development for different application (IAEA, 2020a). As can be expected most of the designs are based on water cooled technology but the number of other designs has been increasing recently. A selection of these designs are summarized in Table 2 for water (and heavy water) reactors and in Table 3 for fast spectrum, HTGR and micro reactors.

Outlook and challenges to deployment

The first and perhaps biggest challenge are commercial demonstration. This requires the development, testing, licensing, construction and operation of a nuclear power plant. Many potential clients, especially from countries that plan to introduce nuclear power for the first time, rightly require a reference plant licensed and operating in the country of origin to limit their financial and technical risks.

The second challenge is to get to a situation where the economy of numbers come into effect. Whereas the power output of large LWR has increased over the years to benefit from economies of scale, the SMR vendor need to build many plants to bring the cost down. The vendor also needs to make a strategic decision when to establish the factory manufacturing facilities to get the benefit of reduced cost and increased quality.

The flexibility requirements on SMRs are expected to increase over time in a deregulated market and with an increased share of intermittent renewables. SMR designers aim to design a reactor module that could be flexible enough to serve many needs, ideally without any design changes. This concept is illustrated in Fig. 2.

Status	Basic engineering in progress	Conceptual	Basic design completed	Conceptual

International Atomic Energy Agency (2020a) *Advances in Small Modular Reactor Technology Developments – 2020 Edition*, https://aris.iaea.org/Publications/SMR-Book_2020.pdf.

Fig. 2 Flexible utilization of SMR modules for different power and heat applications.

This takes the modular concept beyond just the reactor unit and extend it to different non-nuclear modules that can be coupled and configured to fulfil a specific customer needs, be it a heat storage module, a module providing process heat at specific conditions to one or more of multiple possible process heat application, cogeneration, or integration with renewables to perform load following. This can of course be applicable to a single or multiple reactor modules configured in this way. The huge challenge would be to come up with designs that can be licensed and then deployed in different configurations and sites in many different countries.

Excellent progress has been made in clarifying the licensing process of SMRs. Various regulators have established a specific focus on the future licensing of SMRs. The US Nuclear Regulatory Commission (NRC) has worked to developed better guidance for light water based SMRs (NRC, 2010) and more recently on reducing the licensing risks of Advance non-water cooled reactors (NRC, 2018). In Canada, the Pre-Licensing Vendor Design Review (VDR) process has attracted more than 10 SMR submissions (CNSC, 2021). In March 2019, Global First Power applied for a license to prepare a site for a small modular reactor on Atomic Energy of Canada Limited's property at the Chalk River Laboratories location. The plan is to deploy the MMR design of Ultra Safe Nuclear Corporation, a HTR micro-reactor. Regulators in many other countries are also prepared to receive submissions and license e SMRs.

Background

From the more than 70 SMR designs and concepts presently being pursued, at least 20 are of the water-cooled, water-moderated type. These designs are under various stages of development, demonstration, and deployment. In terms of the nuclear steam supply system (NSSS) configuration, they can be categorized into the followings four categories:

iPWRs

The term “integral” refers to integrating (entirely or partially) the primary components within the NSSS, i.e., the steam generators, pressurizer, control rod drive mechanism, and reactor coolant pumps (RCPs) are colocated in inside the reactor pressure vessel in the proximity of the core, hence eliminating the recirculation loop (Belles, 2015; Carelli, 2015). The primary design objectives of this integration are of fourfold:

Simplification: The integral configuration results in reduced nuclear island size and thus enhanced components transportability. Some designs implement horizontally or vertically mounted circulation pumps at the reactor vessel through nozzles, or internally mounted at the bottom of the reactor vessel. Other designs adopt natural circulation for the primary cooling system, thus eliminating the need of heavy recirculation pumps and reducing mechanical complexity. It should also be noted that the internal steam generator has a large heat transfer area in a compact geometry.

Enhanced safety: With only small piping connected to the reactor vessel, integral NSSS configuration enables practical elimination of loss of coolant accidents due to a large pipe break. For integral PWR designs with internal control rod drive mechanism, rod ejection accidents can be precluded. The potential of large and medium breaks, such as hot/cold leg, pressurizer surge line, and primary pump suction/discharge line breaks are eliminated by design.

Improved reliability: The simplified design and consequent enhanced robustness contribute to the improvement of the reliability of integral PWR systems.

Economic Competitiveness: A high degree of modularity of shop fabricated structures, systems and components, as well as the phased deployment of additional modules as demand increases, result in the “economics of multiple” (as oposed to the “economy of scale”) for countries and regions for which large reactors would not be viable, or which are experiencing a slower electricity growth rate.

The integral design, in which, as mentioned, all major components of the primary coolant system are collocated either entirely or partially in the single pressure vessel, enables elimination of piping of the primary cooling system. By contrast, the typical large-rated PWRs are loop systems with the primary system components, e.g., the steam generators, primary coolant pumps and pressurizer connected by piping to each other, and to the pressure vessel which houses the reactor core and the control elements.

One simplistic way to describe an iPWR relative to the current pressurized-water reactor (PWR) designs is “more water—less pipe.” Because of the integral nature of the various iPWR designs, the available water volumes in an iPWR relative to the thermal power rating of the reactors is substantially increased compared with current PWR designs. Furthermore, the size and length of the reactor coolant system (RCS) piping is significantly reduced compared with current PWR designs. This reduces the need for many of the active safety system components found in larger LWRs and generally increases the operator response time to plant upsets.

Differences from current PWR designs and commonalities with PWR designs are highlighted in this article. Except for the option of air cooling, the secondary plant in an iPWR is very similar to the current PWR reactor fleet. Therefore, secondary plant components are fairly common and will not be discussed in detail in this article.

Compact-loop PWRs

The term “compact” indicates the use of conventional loop configuration as applied in the operating medium and large-sized PWRs, but with external vessels for steam generators and pressurizer that are flanged directly to the reactor pressure vessel. This design eliminates the need of recirculation piping in the primary loop. Compact loop is a transition between traditional loop-type and the integral configuration. It is applied in marine-based nuclear power plants, e.g., floating NPP and nuclear icebreaker ships.

Traditional loop-type PWRs

Typical loop-type configuration as applied in the operating medium and large PWR nuclear power plants. A loop would consist of a steam generator, a recirculation pump, and the associated pipings (hot leg, cold leg, and cross-over leg) that connects the components with the reactor pressure vessel.

Boiling water reactors (BWRs)

Direct cycle BWRs with natural circulation, without external pumps or external pipings, adopts predesigned features from the large-sized Economic Simplified BWR, for its primary circuit, or nuclear boiler system. Passive safety features are fully adopted.

“Modular” refers to the unit assembly of the NSSS, which when coupled to a power conversion system or process heat supply system, delivers the desired energy product. The unit assembly can be assembled from one or several submodules. The desired power plant can then be developed from one or several modules as necessary to deliver the desired power rating. Importantly, the deployment of modules can also be sequenced over time both to match regional load growth and to levelize the timing of capital spending over a prescribed timeframe. Construction of the plant by assembly of factory-built elements or modules is the technique of modular construction. Although it is an integral part of the construction strategy envisioned for all SMRs, this technique is not uniquely applied to SMRs. Rather, it is now being employed for relevant construction elements of nuclear power plants of all power ratings, although the modules for large plants are considerably different in size, not typically amenable to ease of transportation and to the rapid assembly as is being proposed for SMRs.

Status of water-cooled, water-moderated SMR design and technology development

Many design organizations pursue integral PWR-type or BWR-type concepts that can form a reactor module or be combined to multi-module SMR power plants. Each module is independent of each other and operated from a common main control room. In this article, the following nine land-based water-cooled water-moderated types of SMRs are described:

- CAREM: a 30 MW(e) integral PWR type SMRs with natural circulation developed by CNEA, Argentina;
- ACP100: a 100 MW(e) integral PWR type SMRs with forced circulation developed by Nuclear Power Institute of China, China National Nuclear Corporation, China;
- NUWARD: a 170 MW(e)/module integral PWR type with forced convection for twin-module configuration SMR plant, jointly developed by EDF, CEA and the Technic Atome, France.
- SMART: a 125 MW(e) integral PWR type SMRs with forced circulation originally developed by the Korea Atomic Energy Research Institute, Republic of Korea, then the design was jointly developed with the King Abdullah City of Atomic and Renewable Energy, Saudi Arabia through shared an Intellectual Property arrangement.
- RITM-200: a 50 MW compact-loop PWR type SMRs with forced circulation already deployed for nuclear icebreakers, developed by OKBM Afrikantov, Russian Federation;
- UK-SMR: a 450 MW(e) three-loop PWR type SMRs with forced circulation, developed by Rolls-Royce, Plc., United Kingdom;
- NuScale Power Module: a 77 MW(e)/module integral PWR type SMRs with natural circulation and full passive safety features for twelve (12) module configuration NuScale power plant, developed by NuScale Power Inc., United States;

- SMR-160: a 160 MW(e) integral PWR type SMRs with natural circulation and full passive safety features, developed by Holtech International, Inc., United States.
- BWRX-300: a 300 MW(e) direct-cycle boiling water reactor (BWR) with natural circulation and full passive safety features, developed by GE Hitachi Nuclear Energy, United States.

Design description of PWR- and BWR-based SMRs

The following sub-sections are providing brief descriptions of the design characteristics and major operational and safety characteristics of the nine representative advanced designs of PWR- and BWR-based SMRs, which qualify as Generation III (advanced evolutionary) or Generation III+ (advanced passive). Detailed information, in particular in terms of the major design objectives, as well as the challenges and opportunities on the path to commercialization can be found in (IAEA, 2020a,b).

Table 1 provides a summary of the main design characteristics of the various reactor concepts that are being investigated.

CAREM

CAREM stands for the Central Argentina de Elementos Modulares developed by the National Nuclear Energy Agency of Argentina (CNEA). CAREM is an integral PWR type SMR designed as a prototype to generate 25 MW(e). CNEA started the development project for CAREM as a new generation SMR design in 1984. The project activities were intensified in 2006 as a national priority. CNEA completed the preliminary safety analyses report for CAREM in 2009 as a pre-requisite for construction. In 2011, site excavation began to prepare for civil engineering work. The first concrete pour for construction was conducted in February 2014. While the construction has experienced several delays, in the beginning 2021 the project is in an advanced stage of construction of about 70% completion on a site near the Atucha unit-2 nuclear power plant and aims for fuel loading and startup commissioning by mid-2023.

The objective of this prototype is to demonstrate the technology that will be used as the basis for commercial Nuclear Power Plant (NPP) versions with larger power ratings of up to 300 MW(e). A unique characteristic of CAREM is the fact that it will operate in natural circulation mode to drive its primary system coolant flow. This eliminates the need for reactor coolant pumps. Its integral nuclear steam supply system consists of 12 helical once-through steam generators that are installed inside the reactor vessel above the core. The hydraulic control rod drive mechanism is also located in the upper part of the reactor vessel. System pressure is controlled and maintained through self-pressurization, so no pressurizer component is required. This self-pressurization feature aims at developing thermal equilibrium of the steam and liquid phases in the reactor vessel dome region. This provides pressure stability in the reactor coolant system under normal operation, power ramps, and abnormal operating occurrences. For the power conversion system, CAREM has a similar approach to that of operating PWRs. During normal operation, pressurized feedwater is supplied by the electrically driven pumps to the 12 helical steam generators.

The **Fig. 1** shows the reactor configuration of CAREM.

CAREM's passive heat removal system is permitting it to achieve a high safety level. For core decay heat removal, CAREM adopts the pressure suppression pool, commonly used in the operating boiling water reactors for fission product scrubbing and absorption of steam blowdown energy. The CAREM suppression pool is located inside the cylindrical containment vessel that constitutes the final defence-in-depth barrier. The adopted key safety features allow mitigation of the consequences of design basis extended conditions, including severe accidents with core melt, during a 36-h grace period. The safety features ensures safe peak cladding temperature in the core in the case of station blackout (SBO) or loss of ultimate heat sink.

ACP100

ACP100 stands for Advanced Chinese PWR-type SMRs to generate 100 MW(e). It is designed as a Generation III advanced reactor by the China National Nuclear Corporation (CNNC) based on the experience in designing and operating the latest PWR technology in China. The ACP100 follows a deployment strategy of multi-purpose SMRs to supply electricity and heat to medium/small grids, islands, remote areas as well as mining industries. This SMR design is also intended to perform seawater desalination to coastal region with difficult access to potable freshwater. ACP100 is an integrated PWR design with forced convection to drive the primary coolant flow. To achieve a high level of safety, passive safety systems are adopted by including features, such as the Passive Decay Heat Removal System (PDHRS) to prevent core meltdown in the case of design basis accident (DBA), beyond DBA and mitigate postulated severe accidents. To enhance safety and security, the reactor building and spent fuel pool are located below ground level, which gives additional protection from external hazards and reduces any release of radioactive materials. To protect the reactor building against large earthquakes and flooding, segregated waterproof reactor compartments are provided.

Fig. 2 depicts the reactor configuration of ACP100.

The ACP100 reactor pressure vessel includes a vertically mounted reactor coolant pump, a magnetic force-type control rod drive mechanism, and a once-through steam generator. The pressurizer is located outside the reactor vessel. The layout of the reactor vessel and equipment is configured to promote natural circulation between the reactor core and steam generator. The 57 fuel assemblies have a conventional 17×17 square PWR fuel configuration. The reactor will be able to operate on a 24-month refueling cycle.

The safety system is composed of a number of passive safety subsystems covering core cooling, residual heat removal, containment spray cooling, and containment hydrogen control, as well as an automatic depressurization system. A large primary coolant

Fig. 1 Reactor configuration of CAREM developed by CNEA, Argentina.

inventory is also included as a safety feature. To protect against an SBO event, there is a 72-h DC battery system to provide power in support of all accident mitigation systems. Auxiliary power units are located inside the reactor building to recharge the batteries for up to 7 days. The ACP100's passive decay heat removal system provides cooling for 72 h without operator intervention or 14 days with water supply from the cooling pool, drained by gravity force.

The plant also has an enhanced spent fuel pool configuration to cope with a loss-of-heat sink event such as what occurred at the Fukushima Daiichi nuclear plant. Even with the pool filled with 10 years' worth of used fuel, the cooling system would be able to cope for 7 days in the case of a severe accident before it would boil dry and uncover fuel.

CNNC began an R&D program for ACP100 in June 2010 with a basic design that was approved in June 2010. At the end of 2013, a preliminary design for the ACP100 was completed that included enhanced safety features that have incorporated the lessons learned from the Fukushima Daiichi accident. In 2014, the PSAR was submitted to the IAEA Department of Nuclear Safety and Security to undertake a Generic Reactor Safety Review. The review lasted for 8 months and resulted in a set of recommendations to enhance the overall performance of the design. In June 2020, the National Nuclear Safety Administration of China (NNSA) approved the PSAR to enable Construction Start Date (CSD) in 2021 in the Fujian Province as a demonstration unit to be in operation in 2026.

NUWARD

Officially launched in 2019, NUWARD is a conceptual design of integral PWR to generate 340 MW(e) from two independent modules that enable flexible operation. This Generation III+ SMR is being developed by a French EDF-led consortium including CEA, TechnicAtome, and the Naval Group. As an integral PWR, the main components of the NSSS including compact steam generators, pressurizer and control rod drive mechanisms are installed within the Reactor Pressure Vessel (RPV) in proximity with the core. Design simplification leads to a shortened RPV that enables the NSSS to be installed in a steel containment vessel submerged in a large volume underground water-wall.

The reference core is based on a proven 17×17 fuel assemblies design used in currently operating PWRs with a shortened core height and UO_2 rods with enrichment $< 5 \text{ wt\% } ^{235}\text{U}$. Various levels of ^{235}U enrichments and burnable poisons are used in the core to achieve a boron-free design. Based on a 2-year refueling interval, fuel handling uses state-of-the-art techniques applied in the operating PWRs. The reactor coolant system of NUWARD uses a newly invented Compact Steam Generator (CSG), once-through steam generator technology derived from the plate heat exchanger concept that allows direct connection to the reactor vessel. The overall size of the reactor coolant system can, therefore, be significantly reduced.

Fig. 3 illustrates the reactor configuration of NUWARD™.

Fig. 2 Reactor configuration of ACP100 developed by NPIC/CNNC, China.

Fig. 3 Reactor configuration of NUWARD™ developed by a consortium of CEA, EDF and TechnicAtome, France.

To achieve high safety performance, NUWARD adopts passive safety systems to cope with Design Basis Conditions (DBC) without the need for any external power supply and is self-reliant on an internal ultimate heat sink for a grace period of more than 72 h. No safety classified 1E electrical power is required (except DC power to I&C). No operator action required for more than 3 days after any design basis accidents (DBA). To cope with severe accidents with core melt, in-vessel retention of the corium (IVR concept) is adopted.

The following inherent features benefit NUWARD in achieving its safety performance goals:

- Large reactor coolant inventory provides inertia in coping with power transients;
- The boron-free operation provides large and constant moderator counter-reaction and is preventing boron dilution;
- The integral NSSS architecture minimizes the pipe break size in LOCA, thus providing more time for mitigation. Internal control rod drive mechanism (CRDM) prevents reactivity accidents caused by rod-ejection;
- A submerged containment provides passive cooling for several days;
- A small core in a large RPV facilitates an in-vessel retention strategy for severe accidents with core melts.

The Nuclear island (NI) houses two independent modules and an associated fuel storage pool. The NI is designed to withstand design basis earthquakes. No heat sink outside the NI is required to ensure the safe-state for at least 72 h. The NI is self-reliant for at least this period due to the water-wall in which each containment vessel is immersed. To account for seasonal variations, the concept of “a set of reactors inside the same plant” provides the operator with a solution to adapt the maintenance schedule with priority given to the electrical grid supply needs. There is always at least one reactor of the plant in operation and supplying the grid, while another reactor may be in maintenance. As twin-module configuration, the reactors are operated from a common control-room with dedicated panels for normal operation.

SMART

The 365 MW(th) System-integrated Modular Advanced ReacTor (SMART), developed by the Korea Atomic Energy Research Institute (KAERI), is an integral PWR with a rated electrical power of 110 MW(e). SMART adopts advanced design features to enhance the safety, reliability and economics. The advanced design features and technologies implemented were verified and validated during the standard design approval review. To enhance safety and reliability, the design configuration incorporates inherent safety features and passive safety systems. Economics improvement is achieved through system simplification, component modularization, reduction of construction time and high plant availability. The advanced design features of SMART include integrated SGs, in-vessel pressurizer, and the horizontally mounted canned motor pumps. SMART is a multi-purpose application reactor for electricity production, seawater desalination, district heating, process heat for industries, and suitable for small or isolated grids. SMART has a unit output adequate to meet the demands of electricity and freshwater for a city of 100,000 inhabitants.

Fig. 4 provides the reactor configuration of SMART.

The SMART design adopts an integrated primary system, modularization and advanced passive safety system to improve the safety, reliability as well as the economics. Improvement in the economics is achieved through a system simplification, in-factory fabrication, reduction of construction time and high plant availability.

SMART has an integral reactor coolant system configuration for the NSSS that enables the elimination of large bore pipe connections resulting in the removal of the large break loss of coolant accident (LOCA) from the design basis events. The NSSS consists of the reactor core, helically coiled steam generators and a pressurizer integrated in the reactor pressure vessel (RPV). The primary cooling system is based on forced circulation during normal operation. The system has natural circulation capability for emergency condition.

The safety systems of SMART are designed as fully passive that function automatically on demand. These consist of a reactor shutdown system, a passive safety injection system (PSIS), PRHRS, a shutdown cooling system and a passive containment cooling system (PCCS). Additional safety systems include reactor overpressure protection system such as automatic depressurization system (ADS) and pressurizer safety valves, and severe accident mitigation system. As a result the reactor safety is enhanced substantially and the core damage frequency is also reduced.

As for the engineered safety system approach and configuration, SMART adopts passive safety features to cope with abnormal operating occurrences and postulated design basis accidents, and severe accidents with core melts. The passive safety system is being developed to maintain a safe shutdown condition following design basis accidents such as LOCA and non-LOCA transient events without AC power or operator actions. The passive safety system consists mainly of PSIS, PRHRS, PCCS, and the automatic depressurization system (ADS). All the active safety features are being substituted with passive versions, eliminating the necessity for emergency diesel generator (EDG) or operator actions for at least a 72 h period.

KAERI received the standard design approval from the Korean nuclear safety commission in July 2012. In September 2015, a pre-project engineering agreement was signed between the Republic of Korea and the Kingdom of Saudi Arabia for the deployment of SMART. A construction period of less than 3 years from the first concrete to fuel load is predicted. A safety enhancement program to adopt a passive safety system in SMART began in March 2012, and the testing and verification of the PRHRS and PSIS were completed at the end of 2015.

RITM-200

The RITM series reactor RITM-200 is the latest development in the Generation III + SMR line designed by the OKBM Afrikanov. It has incorporated all the proven features from its predecessors. The RITM-200 based NPP is a reference technology, currently at

Fig. 4 Reactor configuration of SMART developed by KAERI, Republic of Korea.

a rather advanced development stage and will be available in short/medium term for commercial deployment. RITM-200 based NPP modularity enables to provide power both for commercial/local needs (e.g., in the 100 MW thermal rating range), as well as for regional needs (300 MW). Being initially designed for icebreakers, the RITM series reactors are already responding to the key market requirements, such as small size, long refueling cycle and flexible load following capabilities (100 to 30 to 100% nominal power). Six RITM-200 reactors have been already manufactured for nuclear icebreakers. Four reactors are already installed on the Sibir and the Arktika nuclear icebreakers. Based on these factors, the RITM series reactors are the most optimized solution in terms of size and other technical and economic parameters.

The RITM-200 series reactors are land-based multi-purpose application reactors for electrical power generation, water desalination, and district or industrial heating. RITM-200 based NPPs is suitable for small, isolated, or distributed grids.

The RITM series reactors are the evolutionary development of the reactors (OK-150, OK-900, KLT-40 series) for Russian nuclear icebreakers with a total operating experience of more than 50 years (more than 400 reactor-years). With incorporation of the steam generators into the reactor pressure vessel, the reactor system and containment is very compact compared to the KLT-40. RITM design makes it possible to increase electric output (40% more) and reduces the dimensions (45% less) and the mass (35% less) in comparison with KLT-40S. While integral reactor configuration almost eliminates the classic large loss-of-coolant accident (LOCA) and the other inherent features and active and passive safety systems apply concepts of diversity, redundancy, physical separation, and functional independence to achieve the necessary safety level and reliability.

The RITM nuclear steam supply system consists of the reactor core, four steam generators integrated in the reactor pressure vessel, four canned main circulation pumps (MCP), and pressurizer. The primary cooling system is based on forced circulation during normal operation and allows natural circulation in the case of emergency condition.

For the reactor core, RITM-200M adopts a low enriched cassette core similar to KLT-40S that ensures long time operation without refueling and meets international non-proliferation requirements. The core consists of 199 fuel assemblies with fuel enrichment up to 20%.

The safety concept of the RITM-200 is based on the defence-in-depth principle combined with the inherent safety features and use of passive systems. Properties of inherent safety features are intended for automatic control of power density and reactor self-shutdown, limitation of primary coolant pressure and temperature, heating rate, primary circuit depressurization scope and outflow rate, fuel damage scope, maintaining of reactor vessel integrity in severe accidents and form the image of a “passive reactor,” impervious to possible disturbances. RITM-200 optimally combines passive and active safety systems to cope with abnormal operating occurrences and design basis accidents. More specifically:

- Passive pressure reduction and cooling systems have been included (system reliability is confirmed by test bench);
- Pressure compensation system is divided into two independent groups to minimize size of potential coolant leak;
- Main circulation path of the primary circuit is located in a single vessel;
- Steam header of primary coolant circulation is added, which ensures safety of the plant during SG and MCP failures.

The exposure dose for the staff in normal operation and design basis accidents does not exceed 0.01% of the natural radiation limit. The public exposure dose in case of severe accident is below the value requiring protective measures.

The basic architectural design of the RITM-200M land-based NPP is similar to conventional large NPPs. However, it is housed within a relatively small footprint and includes nuclear island, spent fuel pool, turbine island, auxiliary buildings for water treatment, maintenance, and switchyard connections. The RITM-200 design was developed in conformity with Russian laws, norms and rules for nuclear power plants and safety principles developed by the world community, as well as based on IAEA recommendations.

Fig. 5 shows the RITM-200M reactor configuration.

UK-SMR

Rolls-Royce, Plc. is undertaking SMR design and technology development for a Gen III+ three-loop, close-coupled PWR that provides a power output of 443 MW(e) from 1276 MW(th) using industry standard UO_2 fuel. Coolant is circulated via three centrifugal RCPs to three corresponding vertical u-tube SGs. The design includes multiple active and passive safety systems, each with

Fig. 5 Reactor configuration of RITM-200M designed by OKBM Afrikantov, Russian Federation.

substantial internal redundancy. Rapid, certain and repeatable build is enhanced through site layout optimization and maximizing modular build, standardization and commoditization. The power station is designed for installation on an extensive range of inland and coastal sites, across a wide range of soil conditions. This flexibility is enabled through design features such as seismic isolation for safety related areas. The three-loop PWR is located in the Nuclear Island, adjacent to the Turbine Island with the Cooling Water Pump House following. Support buildings and auxiliary services are situated within a berm that sweeps around the site and provides protection from external hazards such as tsunami or aircraft impact.

Fig. 6 reactor configuration of the UK-SMR.

The plant is capable of load following, operation on house load where required, even a black start in which the plant is capable of restoring an electric power station without relying on the external electric power transmission network. As a result of the passive nature of safety systems, the plant is not reliant on grid power for safety related functions. The UK SMR is primarily intended for electricity production; however, the design can be configured to support other heat-requiring or cogeneration applications.

The UK SMR primary circuit comprises a reactor core, containing the reactor fuel, mounted in an RPV that is closely coupled through large bore pipework to three SGs. Nuclear fission in the reactor core produces heat which is transferred to coolant in the primary loop through thermal conduction and convection. A pressurizer is connected to the primary circuit via a surge line to provide the necessary overpressure to prevent boiling in the reactor coolant circuit.

The reactor core has been sized to optimize power output within an RPV that is sized to maximize road transportability, producing 1276 MW(th). Coolant is transferred via three canned sealless centrifugal RCPs to three corresponding vertical u-tube steam generators, each rated to remove approximately 425 MW(th) during normal power operation. The RCPs are mounted, via close-coupled nozzles, to the bottom of the SG outlet head.

For all Design Basis Accidents (DBA), defence in depth is provided through the provision of robust safety measures, designed against conservative conditions, which meet the guidelines from the deterministic design basis analysis.

Multiple layers of fault prevention and protection are provided through diverse and independent active and passive systems, comprehensively ensuring UK SMR safety for design basis and design extension conditions, for all modes of operation and during all lifecycle stages.

In addition to heat removal via the closed loop SG steam and feed cycle, the Passive Decay Heat Removal (PDHR) system and the Emergency Core Cooling System (ECCS) are passive, redundant, diverse and segregated protective safety measures that provide multiple means of decay heat removal in response to faults.

All design basis Loss of Coolant Accidents (LOCA) are protectable by ECCS, with diverse protection additionally available from the Small Leak Injection System (SLIS) for smaller leaks. Control Rods (scram) and Emergency Boron Injection provide two diverse and highly reliable means of reactor shutdown. Three Safety Relief Valves are provided to protect against over pressure hazards, each fully capable of providing depressurization.

The UK SMR consortium includes among others the National Nuclear Laboratory (NNL), the Nuclear AMRC, and Rolls-Royce, Plc. The consortium aims to have the first UK SMR power station in operation around 2030 in the United Kingdom.

Fig. 6 Reactor configuration of UK-SMR developed by Rolls-Royce, Plc., United Kingdom.

NuScale power module

The NuScale Power Module (NPM) is a small, light water cooled pressurized-water reactor (PWR) developed by the NuScale Power Corporation, United States. The design has received standard design approval from the US Nuclear Regulatory Commission in September 2020. The NuScale design is a modular reactor for electricity production and non-electrical process heat applications. A NuScale nuclear power plant is scalable and can be built to accommodate a varying number of NPMs to meet a customer's energy demands. The 77 MW(e) NPM provides power in increments that can be scaled to 924 MW(e) gross in a single facility. A 12 module configuration is the current reference plant size for design and licensing activities. Each NPM is a self-contained module that operates independently of the other modules in a multi-module configuration, as shown in Fig. 7. All modules are managed from a single control room. The plant design contains the following significant features:

- reliable and passively safe systems that are simple in design and operation;
- safety features that assure a core damage frequency substantially lower than the current light water reactor fleet;

Fig. 7 Reactor configuration of NuScale Power Module developed by NuScale Power Inc., United States of America.

- reactor building designed to protect against aircraft impact while maintaining spent fuel pool integrity and preserving containment integrity;
- 60-year design plant life;
- reduced construction schedule compared to nuclear plants of a comparable output;
- modularization to enable in-shop fabrication of reactor and containment components; and
- use of half-height traditional 17×17 nuclear fuel assemblies.

The NuScale power plant design philosophy is based on the following elements: a design that uses proven light-water reactor technology, modular nuclear steam supply system, factory-fabricated power modules with shippable components, and passive safety systems that allow for unlimited coping time after a design basis accident without power, operator action, or makeup water. The NPM is designed to operate efficiently at full-power conditions using natural circulation as the means of providing core coolant flow, eliminating the need for reactor coolant pumps. The NSSS consists of a reactor core, helical coil steam generators, and a pressurizer within the RPV. The NSSS is enclosed in an approximately cylindrical containment vessel (CNV) that sits in the reactor pool structure. The reactor core is located below the helical coil steam generators inside the RPV.

Each NPM incorporates several simple, redundant, and independent safety features, specifically:

Decay Heat Removal System: The decay heat removal system (DHRS) provides secondary side reactor cooling for non-LOCA events when normal feedwater is not available. The system is a closed-loop, two-phase natural circulation cooling system. Two trains of decay heat removal equipment are provided, one attached to each steam generator loop. Each train is capable of removing 100% of the decay heat load and cooling the reactor coolant system. Each train has a passive condenser immersed in the reactor pool. During normal operations, the condensers are maintained with sufficient water inventory for stable and effective operation.

Emergency Core Cooling System: Emergency core cooling system (ECCS) consists of two independent reactor vent valves (RVVs) and two independent reactor recirculation valves (RRVs). For LOCAs inside containment, the ECCS returns coolant from the CNV to the reactor vessel. This ensures that the core remains covered and that decay heat is removed. The ECCS provides a defence-in-depth means of decay heat removal in the unlikely event of a loss of feedwater flow, combined with the loss of both trains of the DHRS. The ECCS removes heat and limits containment pressure by steam condensation on, and convective heat transfer to, the inside surface of the CNV. Heat is then transferred by conduction through the CNV walls and convection to the water in the reactor pool. Long-term cooling is established via recirculation of reactor coolant to the RPV through the ECCS recirculation valves.

Reactor Pool: The reactor pool is a large stainless steel lined pool located below the plant ground level. Water in the pool provides cooling for the NPM for a minimum of 72 h following any design basis accident. During normal plant operations, heat is removed from the pool through a cooling system and ultimately rejected into the atmosphere through a cooling tower or other external heat sink. In an accident where off-site power is lost, heat is removed from the NPMs by allowing the pool to heat up and boil. Water inventory in the reactor pool is large enough to cool the NPMs for an unlimited time without adding water.

In December 2016, NuScale Power submitted the Design Certification Application (DCA) to the US NRC. The design certification review went on track. The NRC issued a design certification approval (DSA) in September 2020, with final design approval (FDA) in 2021. The first plant owner, the Utah Associated Municipal Power System (UAMPS) has target commercial operation date of 2029 for the first module, to be built in Idaho.

SMR-160

The SMR-160 conceptual design has been developed by the US company Holtec International as an advanced PWR-type small modular reactor producing power of 525 MW(th) or 160 MW(e) and adopting passive safety features. Simplification in the design is achieved by using fewer valves, pumps, heat exchangers, instrumentation, and control loops than conventional plants, simplifying operator actions during all plant modes, including diagnosing and managing off-normal and accident conditions. The SMR-160 uses fuel similar to existing commercial LWR fuel, includes no reactor coolant pumps and utilizes a large vertical steam generator. A modular construction plan for SMR-160 involves pre-assembling the largest shippable components prior to arrival at a site. A 24-month construction period is envisaged for each unit.

Fig. 8 depicts the reactor configuration of the SMR-160.

The primary application of SMR-160 is electricity production with optional cogeneration equipment (i.e., hydrogen generation, district heating, and seawater desalination). Target applications include distributed electricity production, repowering coal facilities, uprate for existing nuclear facilities and providing electricity and low-temperature process heat for commercial and military installations. Design optimization includes air-cooled condensation for no wet cooling. The plant design includes a unique fuel management solution that incorporates an integrated state-of-the-art underground dry fuel storage facility with the base plant offering.

The SMR-160 is a pressurized water reactor with the RCS using natural circulation for all power and accident modes and states. The RCS is comprised of the RPV and a SG in an offset configuration with an integrated pressurizer flanged to the top of the steam generator. The RPV and the SG are connected by a single connection that houses both the hot leg and the cold leg. The hot leg is the inner pipe and the cold leg is the annular region of this single connection. Unique among integrated PWRs, the offset configuration allows easy access to the core without moving the RPV or SG during refueling. The SG has a superheating feature which eliminates

Fig. 8 Reactor configuration of SMR-160 developed by Holtec International Inc., United States of America.

the need for a moisture separator reheater and trains of feedwater heaters, while not compromising the thermodynamic efficiency of the plant. The secondary side has only two feedwater heaters simplifying plant operations and maintenance.

The SMR-160 employs an efficient core design that uses traditional reload shuffle at the end of each cycle. The core is designed for up to a 2-year cycle with flexibility for shorter cycles depending upon utility requirements. Because of the relatively low number of fuel assemblies and overall outage schedule, the shuffling of nuclear fuel is not a critical path activity during an outage. The core contains an array of 96 square-lattice assemblies having an area of approximately 35.5 cm^2 , and an 4.3 m active height. Fuel bundles are surrounded by 16 reflector assemblies that contain pins of solid stainless steel or other reflecting material contained within stainless steel tubes. The reflector assemblies allow for an axial variation in the radial reflector by varying the composition of the pins along their length. The reflector assemblies can also be changed on a cycle to cycle basis if necessary depending upon fuel utilization requirements. Surrounding all of the fuel and reflector assemblies is a solid stainless steel reflector structure. This provides reflection of fast neutrons in order to improve the neutron economy, while reducing the fast neutron fluence through the reactor pressure vessel thereby, increasing vessel life.

To achieve the desired safety performance, the SMR-160 safety basis incorporates defence-in-depth via multiple and diverse simple pathways for heat rejection from the core. All safety systems are within the containment structure (CS), making them secure and safe from external threats. A large inventory of water within a reservoir outside the containment structure provides long-term post-accident coping, and that structure facilitates air cooling for decay heat removal if the reservoir inventory boils off; for an unlimited coping period. SMR-160 engineered safety features include the passive core cooling system (PCCS), passive spent fuel pool cooling system (PSFPCS), and automatic depressurization system (ADS).

The SMR-160 ICS consists of a free standing steel containment vessel called the CS, supported within a reinforced concrete reactor building called the containment enclosure structure (CES), which also provides a missile protection. An annular coolant reservoir between the CS and the CES is filled with water and serves as the UHS for SMR-160. In addition to preventing the release of radioactive fission products to the environment, the ICS acts as a large passive heat exchanger to cool the core and the spent fuel pool. The PCCS and PSFPCS are connected to the integrated containment system (ICS) via the CS metal surface to reject heat to the environment, which is the plant ultimate heat sink (UHS). The reservoir provides sufficient inventory to remove the peak decay heat; as the water in this reservoir depletes (reservoir becomes dry > 60 days), the ICS transitions to air cooling to remove subsequent decay heat. The operator has the option of replenishing the reservoir.

BWRX-300

GE Hitachi Nuclear Energy's (GEH's) BWRX-300 is a 300 MW(e) water-cooled, natural circulation SMR utilizing natural phenomena driven safety systems. The BWRX-300 is an evolution of the U.S. NRC-licensed, 1520 MW(e) ESBWR. It is designed to provide clean, flexible energy generation that is cost competitive with natural gas-fired power plants. Target applications include baseload electricity generation, load following electrical generation within a range of 50–100% power and district heating.

Fig. 9 shows the BWRX-300 reactor configuration.

The key features of the BWRX-300 include:

- 10th generation BWR technology.
- 300 MW(e) SMR.
- Compliance with the international high safety standards.
- Designed to be cost competitive with gas.
- Up to 60% capital cost reduction per MW.
- Evolved from the licensed ESBWR.
- Designed to eliminate large-break LOCA.
- Reduced on-site staff and security.
- Proven components, fuel, and supply chain.
- Constructability integrated into design.

BWRX-300 is being designed with the proven supply chain of the ABWR, and predesigned features from the ESBWR, for its primary circuit, or nuclear boiler system. The primary functions of the nuclear boiler system are:

- To deliver steam from the RPV to the turbine main steam system;
- To deliver feedwater from the condensate and feedwater system to the RPV;
- To provide overpressure protection of the reactor coolant pressure boundary (RCPB);
- To provide the instrumentation necessary for monitoring RPV pressure, steam flow, core flow, water level, and metal temperature.

The RPV has a minimum inside diameter of 4 m, a wall thickness of about 136 mm with cladding, and a height of 27.4 m from the inside of the bottom head (elevation zero) to the inside of the top head. The bottom of the active fuel location is 5.2 m from elevation zero and the active core is 3.8 m high. The relatively tall vessel, due to the chimney, permits natural circulation driving forces to produce abundant core coolant flow.

The major reactor internal components include:

- core (fuel, channels, control rods and instrumentation),
- core support structures (shroud, shroud support, top guide, core plate, control rod guide tube and orifice fuel support),
- chimney
- chimney head and steam separator assembly,
- steam dryer assembly,
- feedwater spargers,
- in-core guide tubes.

Fig. 9 Reactor configuration of BWRX-300 developed by GE Hitachi Nuclear Energy, United States of America.

Containment/confinement

The BWRX-300 Primary Containment Vessel (PCV) is a metal tank that encloses the RPV and is related systems and components. The PCV is dry and is located mostly below grade. The dry PCV is a leak tight gas space surrounding the RPV and the reactor coolant pressure boundary.

Isolation condenser system (ICS)

The isolation condenser system (ICS) removes decay heat after any reactor isolation during power operations also provides over-pressure protection in accordance with ASME BPV code, section III, class 1 equipment. Decay heat removal limits further increases in steam pressure and keeps the RPV pressure low. The ICS consists of four independent loops, each containing a heat exchanger, with a capacity of 33 MW(th), that condenses steam on the tube side and transfers heat by heating/evaporating water in the IC pool, which is vented to the atmosphere.

The ICS is initiated automatically, and the ICS will also be initiated if a loss of DC power occurs. To start an Isolation Condenser (IC) into operation, the IC condensate return valve is opened whereupon the standing condensate drains into the reactor and the steam-water interface in the IC tube bundle moves downward below the lower headers. The ICS can also be initiated manually by the operator from the MCR by opening the IC condensate return valve. The IC pool has an installed capacity that provides 7 days of reactor decay heat removal capability. The heat rejection process can be continued indefinitely by replenishing the IC pool inventory. The ICS passively removes sensible and core decay heat from the reactor when the normal heat removal system is unavailable. Heat transfer from the IC tubes to the surrounding IC pool water is accomplished by natural convection, and no forced circulation equipment is required.

Table 2 Expectation for enhanced safety of iPWR type SMRs (Hidayatullah et al., 2015).

Features	Added values to design	Expected safety improvements
Low core power	- Reduces fission product source term - Low level of decay heat and, therefore, would require less cooling after reactor shutdown	- Enhances in-vessel corium retention - Reduces accident consequences - Simplifies emergency planning
The RCS integrated within the RPV	- No large external primary coolant piping - Longer RPV lifetime due to reduced fast neutron fluence	Lower or eliminate susceptibility to certain potential events, such as LBLOCA
Once-through helical coil integrated steam generator with feedwater and steam inside the tube	- Steam generator is designed to withstand the primary pressure without pressure in the secondary side - Steam system is designed to withstand primary pressure up to isolation valves - Steam generator tubes are in compression - Reduced tube-side water inventory	- Improved steam generator tube integrity with steam generator tube rupture frequency reduced - Excessive cooling during a steam line break accident: the addition of reactivity would be limited and the reactor over power may not compromise critical safety limits, due to small secondary water inventory hence heat removal
Natural circulation	Simplified design and reduced maintenance costs, due to the absence of main coolant pumps	- Eliminate loss of flow accident (LOFA) - Eliminates reactor coolant pump accidents (shaft breaks, seal leakage, pump seizure and pump leaks)
Passive safety systems	- The passive safety systems mitigate or potentially eliminate the need for external power under accident conditions - The auxiliary feedwater system may not be required - Spray systems are not required to reduce steam pressure or to remove radioiodine from containment	- Station-black-out (SBO) can be coped - Active safety systems are not required (low core damage frequency) - Removal of core heat without an auxiliary feedwater system may be a significant safety enhancement - No safety-related pumps for accident mitigation; therefore, no need for sumps and protection of their suction supply
Internal CRDMs	- Elimination of rod ejection event - Elimination/reduction of vessel head penetrations	Reactivity initiated accident (RIA) due to rod ejection is precluded
High pressure design, temperature and evacuated metallic containments	- Containment pressure and temperature for worst-case design basis accident remains below containment design values - All water lost from RPV stays within containment and returns to reactor vessel by passive means - More sub atmospheric pressure during normal operation - The engineered safety systems are simplified - Improve seismic capability	- No postulated small-break LOCA (SBLOCA) capable of uncovering nuclear fuel - Containment integrity assured (due to the metallic containment vessel, molten core concrete interaction is not applicable) - The deep vacuum enhances steam condensation rates for containment heat removal during a postulated SBLOCA - Prevent Hydrogen explosion during a severe accident as little Oxygen will be available
Soluble Boron free core	- No Boron dilution - Less corrosion - Reduces volume of liquid radwaste - Strong negative moderator temperature coefficient - Boron monitor and adjustment systems eliminated	- Reactivity-initiated events are precluded - Reduced occupational radiation dose - Improve reactor transient performance as well as operational safety

Passive containment cooling system (PCCS)

The PCCS is a passive system that removes the decay heat and maintains the containment within its pressure limits for design basis accidents such as a LOCA. It consists of several low-pressure, totally independent heat exchangers suspended in the PCV. The heat in the PCV is transferred to the Reactor pool which is located above the PCV upper head, and which is filled with water during normal operation. The Reactor pool is vented to the atmosphere. PCCS operation requires no sensing, control, logic or power actuated devices for operation. The PCCS condensers are a closed-loop integral part of the containment pressure boundary. Since there are no containment isolation valves between the PCCS condensers and the drywell, they are always in “ready standby” mode.

Expectation of safety enhancement in integral PWR type SMRs

The integral PWR type SMRs with modularization are designed for cost reduction and further safety enhancements. Safety improvements are achieved through design simplicity, incorporation of passive safety systems, small fuel inventory, and use of additional fission product barriers. The NSSS with integral module configuration eliminates external coolant loop piping, thus eliminating the large-break loss-of-coolant accident (LBLOCA) scenario. The passive engineered safety features (ESFs) eliminate the need for external power under accident conditions. The expectations for improved safety of iPWR type SMRs are listed in **Table 2** below. The expected core damage frequency (CDF) will be much less and may be of the order of 10^{-6} – 10^{-8} per year or even lower. The CDF of the order of 10^{-8} per reactor-year has been claimed by vendors so far (IAEA, 2016).

Background

Small and medium-sized power reactors (SMRs) are not only being developed for inland on-the-grid and off-shore constructions, but also for floating nuclear power plant (FNPP) and off-grid applications, including oil and gas rigs far from the shore. FNPP with SMRs have the potential to open up new market segments in countries wishing to adopt nuclear energy for various off-grid applications. Small-sized reactors are intended for the remote or isolated regions where the hydrocarbon fuel delivery cost is very high, in which electricity networks are either absent or underdeveloped. By the same token, FNPPs with SMR are options for regions where large capacities are not required, and where consumers are establishing the demands for reliable electricity supply systems, as well as

for alternatives to hydrocarbon based energy production. FNPPs are also a potential power producer for mining, oil and gas industries in different region.

Traditionally, Russia has deployed and is operating marine-based units with SMRs for nuclear icebreakers. The success and lessons-learned from operating nuclear icebreakers are incorporated in the development of FNPP. The technology developer classifies FNPP based on SMR as follows (Fadeev, 2014a, b):

- By the power capacity of a single module (in line with the IAEA power definition): Small power units are designs rated up to typically 300 MW(e); and medium-sized power units are designs that produce between 300 and 700 MW(e);
- By the energy consumption sectors, which means:
 - Local Sector with 1–20 MW(e) SMRs: the sector is isolated from the Russian energy system and other energy sources; it consists of one NPP and one or several consumers;
 - Territorial Sector with 20–100 MW(e) SMRs: the sector is centralized; isolated from the Russian energy system; consists of several sources and consumers;
 - Regional Sector with 100–700 MW(e): this sector is centralized; it consists of balanced sources and consumers; connected to the Russian energy system.

The deployment of SMR NPPs in the Russia is in line with the development strategy for the Arctic region, and a promising market niche. Its foundation in terms of proven technologies and past developments can be outlined as follows:

- (i) Long experience in development and operation of marine-based nuclear power plants. OKBM Afrikantov has designed and supplied reactors for nuclear submarines up to the 4th generation, as well as for surface naval ships with VVER reactors, that have accumulated a total operating time of over 9500 reactor-years. The R&D activities are focused on engineering standardization for the entire power range; enhancing the reliability, safety, and manoeuvrability; as well as on enhancing maintainability by reducing maintenance scope and expanding the service operation between maintenance outages.
- (ii) Long experience in the development and operation of reactor plants for nuclear icebreakers, with a total number of 20 reactors (including 8 installed on current nuclear icebreakers). More than 50 years operation of three generations of nuclear icebreakers in the Arctic region, amounting to a total operating time of more than 365 reactor-years. Design of an innovation SMR for the multipurpose nuclear icebreaker of the 4th generation (RITM-200M).
- (iii) Experience with R&D, design and fabrication of reactor plants for the FNPP: Within 3 years two KLT-40S reactors were supplied for the FNPP “Academician Lomonosov” confirming the efficiency of combining the functions of chief designer and complete supplier.

This shows that proven reactor technologies and innovative solutions are available for countries and utilities with specific needs of floating NPPs with SMRs.

Status of SMR technology development for floating nuclear power plants

In addition to land-based integral-type PWR-type designs that could be deployed as a single reactor module or combined to multi-module SMR NPPs in which each module is independent and operated from a common main control room, there are efforts to develop SMR floating power concepts. In this chapter, six marine-based water-cooled, water-moderated SMR types for floating power plants are described (IAEA, 2020a, b).

- KLT-40S: a 35 MW(e) compact-PWR type SMR for the Akademik Lomonosov Floating NPP that is in operation since December 2019 using two reactor modules producing 70 MW(e);
- RITM-200M: a 50 MW(e) integral-PWR type SMR developed by OKBM Afrikantov as the next generation after KLT-40S for small, isolated, or distributed grids. Six RITM-200 units have been manufactured for nuclear icebreakers. Four reactors are already installed on the Sibir and the Arktika icebreakers;
- ABV-6M: a 6–9 MW(e) per module integral-PWR type with natural circulation primary cooling for shipyard fabricated, multipurpose, transportable NPP designed for safe operation over 10–12 years without refueling at the berthing platform or along the coast, developed by OKBM Afrikantov;
- VBER-300: a larger 325 MW(e) integral-PWR type developed by OKBM Afrikantov, to supply thermal and electric power to remote areas where centralized power is unavailable, and to substitute capacities of fossil fuels for cogeneration, deployed both as land-based or floating marine-based;
- ACPR-50S: a 50 MW compact-loop PWR type SMRs with forced circulation already deployed in nuclear icebreakers, developed by the China General Nuclear Power Group (CGNPC);
- SHELF: a 28.4 MW(th)/6.6 MW(e) integral PWR, as power source for remote and hard-to-reach locations with decentralized power supplies, developed by NIKIET.

Design description of SMR-based floating nuclear power plants

The following sub-sections are providing brief descriptions of the design characteristics and major operational and safety characteristics of the six representative advanced designs of marine-based PWR-type SMRs for floating nuclear power plants or units. Detailed

information, in particular in terms of the major design objectives, as well as the challenges and opportunities on the path to commercialization can be found in IAEA (2020a, b).

Table 1 provides a summary of the main design characteristics of the various reactor concepts that are being investigated.

KLT-40S

The KLT-40S is a PWR-type SMR developed for the “Akademik Lomonosov” FNPP to produce 70 MW(e) from two reactor modules. The FNPP has started its commercial operation in May 2020 in the Pevek Region, Russia, after it was connected to the grid in December 2019. The KLT-40S is based on the commercial KLT-40 marine propulsion plant and is an advanced variant of reactor plants that power nuclear icebreakers. The “Akademik Lomonosov” FNPP, featuring the two KLT-40S reactors, was manufactured in shipyards and then delivered to the customer fully assembled, tested and ready for operation. It can be moored in any coastal region.

Fig. 1 shows the reactor configuration of the KLT-40S.

The reactor is a modular design with the core, steam generators (SGs) and main circulation pumps connected with short nozzles. The reactor has a four-loop system with forced and natural circulation, a pressurized primary circuit with canned motor pumps and leak tight bellow type valves, a once-through coiled SG and passive safety systems. Fuel utilization efficiency is provided by the use of all improvements of nuclear fuel and fuel cycles of nuclear icebreaker reactors, spent fuel reprocessing and the increase of fuel burnup through the use of dispersion fuel elements.

One of the advantages is long-term autonomous operation in remote regions with a decentralized power supply. The design requires that after every 3–4 years of operation the reactor is refueled. The used nuclear fuel is then stored on board the FNPP, and no special maintenance or refueling ships are necessary.

The KLT-40S is designed with proven safety solutions such as a compact structure of the SG unit with short nozzles connecting the main equipment, without large diameter primary circuit pipelines, and with proven reactor emergency shutdown actuators based on different operation principles, emergency heat removal systems connected to the primary and secondary circuits, elimination of weak design points based on the experience of prototype operation and use of available experimental data, certified computer codes and calculation procedures.

The keel of the first FNPP carrying the KLT-40S, the “Akademik Lomonosov,” was laid in 2007. The “Akademik Lomonosov” was completed in 2017. The FNPP was moored in Pevek, Chukotka region of Russia for the connection to the grid in December 2019 and launched for commercial operation in May 2020 producing 70 MW(e).

RITM-200M

The RITM-200M is designed by OKBM Afrikantov as an integral reactor with forced circulation for use in nuclear icebreakers. For the next deployment, RITM-200M is designed for land-based and floating-based multi-purpose application reactors for electrical power generation of 50 MW(e) per module, water desalination, and district or industrial heating.

Fig. 2 depicts the reactor Configuration of the RITM-200M.

It employs a low enriched cassette type reactor core similar in design to the KLT-40S. The uranium oxide fuel enrichment is up to 20 wt% ^{235}U , and the reactor houses 199 fuel assemblies. The design also allows for a low fluence on the reactor vessel.

The reactor is designed as an integral vessel with the main circulation pumps located in separate external hydraulic chambers and with side horizontal sockets for steam generator (SG) cassette nozzles. The four section SGs have 12 rectangular cassettes, while the four main circulation pumps are located in the cold leg of the primary circulation path and separated into four independent loops. The reactor is also designed to use forced circulation of the primary coolant and an external gas pressurizer system. The SGs produce steam of 295 °C at 3.82 MPa flowing at 248 ton per hour.

The core is designed to operate for 7 years at a 65% capacity factor before the need for refueling. The assigned service life of the plant for replaceable equipment is 20 years with a continuous operation period of 26,000 h; for permanent equipment it is double that. The RITM-200 is designed to provide 30 MW of shaft power on a typical nuclear icebreaker and can be used on vessels of 150–300 t displacement. The reactor can be considered for floating heat and power plants, power and desalination complexes, and offshore drilling rigs. The designers also claim that the overall size of the steam generating unit allows transportation of the reactor by rail. The reactor plant in containment has a mass of 1100 t and is 6 m × 6 m × 15.5 m.

The Atomenergomash, as the primary manufacturer for nuclear reactor components has signed a contract for the supply of RITM-200M reactor units for two more nuclear icebreakers. The contract was signed between the Atomenergomash subsidiary OKBM Afrikantov and the Baltic Shipyard. The new vessels will join the LK-60 icebreakers Arktika, Sibir and Ural, which are dual-draught (8.55 or 10.5 m) wide-beam (34 m) ships of 25,450 dead weight or 33,540 dead weight with ballast, able to handle 3 m of ice. They each have two RITM-200 reactors of 175 MW(th) each, delivering 60 MW(e) at the propellers via twin turbine-generators and three motors. Arktika is expected to enter operation in 2020, Sibir in 2021 and Ural in 2022.

ABV-6M

The ABV-6M reactor installation is a nuclear steam generating plant with an integral pressurized LWR and natural circulation of the primary coolant. The ABV-6 M design was developed using the operating experience of the Russian water-cooled, water-moderated power reactors (VVERs) and has incorporated all the lessons-learned in the field of NPP safety. The main mission of the ABV-6M is to offer multipurpose power sources based on proven marine reactor technologies, providing easy transport to the site, rapid assembly, and safe operation.

Fig. 1 Reactor Configuration of KLT-40S developed by OKBM Afrikantov.

Fig. 3 shows the reactor configuration for the ABV-6M.

The reactor is designed to produce 45 MWt and 8.6 MWe in condensation and 14 MWt and 6 MWe in cogeneration mode. The reactor operates under the normal PWR conditions of 15.7 MPa in the reactor pressure vessel. The steam generators (SGs) located inside the vessel generate 290 °C steam at 3.14 MPa flowing at 55 t per hour.

The reactor cover is set under biological shielding and the control rod drive mechanism is located above the shield outside the vessel. The main reactor pump equipment is arranged on the shield tank as a single steam generating aggregate (SGA) that is transportable by rail. The SGA has a mass of 200 t and is 5 m long by 3.6 m wide with a height of 4.5 m.

The core lifetime without reloading or shuffling of fuel is 10 years with 16,000 h of continuous operation.

Specifically, the ABV reactor installation is intended as a universal power source for FNPPs. The reactor is designed with the capability of driving a floating unit with a maximum length of 140 m, a beam of 21 m, a draft of 2.8 m and a displacement of 8700 t. Depending on the needs of the region, the FNPP can generate electric power, or provide heat and power cogeneration, or heat generation for seawater desalination, or can be used for other applications.

Fig. 2 Reactor Configuration of RITM-200 developed by OKBM Afrikantov.

The ABV-6M reactor is fabricated as a large ready-made unit that is transported by special truck or waterway to the shipyard. The total reactor module has a mass of 600 t and is 13 m in length and 8.5 m in diameter. This allows for a small footprint for the plant building, which would be approximately 67 m long and 47 m wide.

VBER-300

The VBER-300 reactor is a medium sized power source for land based NPPs and nuclear cogeneration plants, as well as for floating NPPs. The VBER-300 design is a result of the evolution of modular marine propulsion reactors. The design was developed using the operating experience of VVER type reactors and achievements in the field of NPP safety. Features of the VBER-300 include the use of proven nuclear ship building technologies, engineering solutions and operating experience of VVER reactors as well as the possibility to enlarge or reduce the source power using only unified VBER-300 equipment (reactors consisting of two, three or five loops).

Fig. 4 shows the reactor configuration of the VBER-300.

The VBER-300 design concept allows a flexible fuel cycle for the reactor core with standard VVER fuel assemblies (FAs). The fuel cycles are 3×2 years and 4×1.5 years. The number of FAs in the refueling batch is either 15 or 30; maximal fuel burnup does not exceed 60.0 MWd/kg U for the cycle with 30 fresh FAs in the reloading batch and maximum initial uranium enrichment. The main reactor coolant pump is an axial, single-stage canned motor pump with experience from operation of more than 1500 main circulation pumps on ships. The steam generators are once-through modules with the secondary coolant flowing within the tubes.

The safety assurance engineering solutions incorporated into the design are: prioritization of accident prevention measures, design simplification, inherent safety, and the defense in depth principle; passive safety systems and enhancement of safety against external impacts (including acts of terrorism); and limitation of severe accident consequences. The VBER-300 emergency shutdown system consists of the control rod drives, two trains of liquid absorber injection, and two trains of boron control from the make-up system. The ECCS consists of two stages of hydraulic accumulators and the RHR system consists of two passive emergency heat removal systems and a process condenser. The estimated reactor unit strength holds up against seismic impacts of maximum magnitude VIII on the MSK-64 scale.

The VBER-300 preliminary design was completed in 2002, and a technical and commercial proposal (a shorter version of technical and economic investigation) for construction of a land based or floating NPP with the VBER-300 was prepared. The preliminary design passed the branch review by Rosatom and was approved by the Scientific and Technical Council. Currently, there are

Fig. 3 Reactor Configuration of ABV-6 M developed by OKBM Afrikantov.

two directions of further project development: first, within the framework of scientific and technical cooperation between the Russia and Kazakhstan, and second, replacement of ageing NPP in Russia. Kazatomprom JSC of Kazakhstan completed a feasibility study for the VBER-300 in Aktau city in 2009 and planned to start construction.

ACPR-50S

Rated at 200 MW(th) and 50 MW(e), the ACPR-50S is a small modular offshore floating reactor developed by the China General Nuclear Power Corporation (CGNPC). It is intended as a flexible solution for combined supply of heat, electricity and fresh water for marine resource development activities, energy supply and emergency support on islands and along the coastal area, (IAEA, 2020a, b).

Fig. 5 displays the reactor configuration of the ACPR-50S.

As an offshore floating SMR, the ACPR-50S is designed as a multipurpose power reactor for the following applications: combined energy supply for offshore oil drilling platform; offshore combined energy supply; coastland and island combined energy supply; energy supply for offshore mining, nuclear power ship; and distributed clean energy for islands together with solar energy and wind power.

The ACPR-50S adopts design simplification to reduce cost and investment risks to be competitive with conventional offshore energy sources. Modular design is adopted through standardized and streamlined manufacturing, aiming for shorter construction period as well as lower cost.

The compact loop-type PWR NSSS design of the ACPR-50S consists of the reactor pressure vessel (RPV) that houses the core, two once-through steam generators (OTSG), two main reactor coolant pumps (RCP) and a pressurizer (PZR), all of which are interconnected by short reactor coolant system legs. The compact layout of the primary loop reduces the probability of LOCA significantly. The system has natural circulation capability for heat removal capacity when operating of up to 10% thermal power.

The low power density design with a low enriched UO_2 fueled core ensures a thermal margin of greater than 15% to the departure to nuclear boiling in the core which can accommodate any anticipated transient event. The 37 fuel assemblies (FAs) of ACPR-50S core, with an axial length of 2.2 m, have a square 17×17 configuration. The reactor will be able to operate 30 months per fuel cycle.

Fig. 4 Reactor Configuration of VBER-300 developed by OKBM Afrikantov.

CGNPC has completed the preliminary design work of the ACPR-50S and is now preparing for detail design. The National Nuclear Safety Administration (NNSA) is performing safety review for this SMR. The ACPR-50S planned to apply for the construction permit to the NNSA in 2020. An industrial demonstration plant of ACPR-50S is being planned to be constructed in China, with a target of startup commissioning in mid of 2020s.

SHELF

SHELF is designed by NIKIET as a local power source for users in remote and hard-to-reach locations. The power unit is a power capsule to generate 6.6 MW(e). The power capsule is developed in two options: containing only all reactor components, and the capsule of a bigger size that includes also the turbine generator package (TGP), the automated and remote-control system,

Fig. 5 Reactor Configuration of ACPR-50S designed by CGNPC.

monitoring and protection system and the electricity output regulation. The SHELF power capsule can be used as both, a floating and a submerged nuclear power plant.

Fig. 6 shows the configuration of the SHELF reactor.

Depending on the customer requirements, the SHELF plant can be equipped with a system for direct heat supply to resident and production premises with a capacity of 12 Gcal/h, or a desalination plant with a capacity of 500 m³/h of fresh water. In case of the land based plant, the heat is removed by external heat exchangers cooled by mechanical air pumping. The SHELF plant does not require local water sources.

Fig. 6 Reactor Configuration of SHELF developed by NIKIET.

SHELF is a water-cooled reactor of integral layout with combined (forced and natural) coolant circulation modes. The fuel campaign is 6 years at a capacity factor of 80%. The components for SHELF are assembled inside a cylindrical power capsule with an inner diameter of 8 m and a length of 14 m. The unit's external systems include an automated instrumentation and control system (AICS) and uninterrupted power supply systems.

The core is of the heterogeneous cartridge type and consists of 163 hexahedral fuel assemblies (FA) of three different types. A number of FAs contains burnable poison and control absorber rods. Absorber rods for reactivity control are united in six identical shim groups.

High level safety is achieved through the following features:

- Use of an integral water-cooled water-moderated reactor with well-developed intrinsic self-protection properties and the following inherent features:
- A defense-in-depth system of barriers to the spreading of ionizing radiation and radioactive products of uranium fission into the environment.

The licensing of the nuclear plant design was scheduled for 2019–2020. During 2017 to 2019, the detailed design was performed for the SHELF power capsule with an electric power of 6.6 MW.

Major challenges ahead and R&D approaches to resolve them

With the deployment of the Akademik Lomonosov FNPP using 2 units of KLT-40S in Pevek, Russian Federation, referenced-design and –deployment projects are now available for countries interested to consider FNPP for their specific conditions. The rationale of the development of FNPP using SMRs is to offer a factory-fueled and tested, transportable nuclear facility for generating electricity and heat in remote regions and small islands where land-based facilities would not be viable. The major challenges ahead lie in addressing legal and institutional issues linked with the deployment of marine-based SMRs when categorized as transportable NPPs (IAEA, 2013). These include preparedness of legal and regulatory frameworks, nuclear safety, security, liability and safeguards and transboundary aspects of Transportable NPPs (TNPP). Implications of floating NPPs on the infrastructure of the recipient countries ought also to be examined. The R&D on both ships or marine platforms with nuclear reactors is quite established. By the same token, the R&D for water-cooled SMRs on floating NPPs is also mature. A recent trend has been to increase R&D aiming at investigating the viability of SMRs based on high temperature and of molten salt reactor technologies for floating NPP, modelling of heat and electricity cogeneration, and commercialization issues.

VHTR Very High Temperature Reactor.

Introduction

Pebble bed gas cooled reactors are part of High Temperature Gas-cooled Reactors (HTR or HTGR (Fütterer et al., 2021)). They are helium-cooled graphite-moderated nuclear fission reactors utilizing fully ceramic fuel. All pebble bed reactor designs considered since the late 1980s applied the same principles established in the HTR-Module design (Reutler and Lohnert, 1984) that ensure no significant or early radioactivity (or radionuclide) releases under all accident conditions.

In general, the pebble bed gas cooled reactor technology is seen as mature. Two pebble bed reactors, the AVR and THTR-300 in Germany, have operated in the past, one test reactor (the HTR-10 in China) is current in operation and a commercial demonstration plant (the HTR-PM with two reactor units) is currently being commissioned in China. The Very High Temperature Reactor (VHTR) has been selected as one of the six Generation-IV International Forum reactor systems and investigates long term concepts aiming at increasing the helium outlet temperatures above 950 °C to reach even higher efficiency and to service the niche of very high temperature process heat markets.

More details on the development of HTR technology can be found in a recent authoritative summary (Kugeler and Zhang, 2019).

The reactor system

The nuclear steam supply system

The pebble bed SMR core is made up by loosely packed fuel spheres loaded into the core cavity formed by the graphite top, bottom and side reflectors. The graphite serves as a neutron reflector but also as the neutron moderator and the main core structural material. The pebble fuel is typically 60 mm in diameter and typically contains between 10,000 and 15,000 TRISO coated fuel particles (Helmreich, 2021) within the inner part of the fuel sphere surrounded by an outer ‘fuel free’ protective layer, all formed from graphitic material. This is illustrated in Fig. 1 (derived from Venter, 2010) with the fuel sphere’s components shown and as loaded into a cylindrical core.

The core geometry is generally cylindrical, tall and slender but can also be an annular shape (with a fixed (or dynamic) cylindrically-shaped central graphite reflector). The core volumes are relatively large and at the upper scale of designs (250–425 MW_{th}) the core may contain nearly half a million fuel spheres. The large core volume limits the power density to 3–6 MW/m³ and a tall and slender core increases the heat transfer from the fuel to the environment so that no active cooling is needed in case of loss of coolant accidents and decay heat can be transferred passively through a non-insulated steel reactor pressure vessel to coolers outside of the reactor (Reutler and Lohnert, 1984; Kugeler and Zhang, 2019; Said et al., 2006). The small core diameters also shortens the heat transfer path from the core radial center to the reactor vessel thus limiting maximum fuel temperatures in accident conditions.

In this severe loss of all active cooling as well as coolant condition only a very small volume of the core may reach temperatures above 1500 °C and this is still far below the temperatures where any failures are expected. Historically, pebble fuel has been tested for accident conditions up to 1600 °C for several days without any significant failures (IAEA, 2010). More recently these heat-up tests were also repeated for the newly manufactured HTR-PM pebble fuel elements (Freis et al., 2020) and for TRISO coated particles up to temperatures of 1800 °C and beyond, with good results (EPRI, 2020).

Fuel spheres are added to the top and extracted at the bottom of the core through a defuel chute (see Fig. 2 left). The bottom cone angle and defuel chute diameter can be chosen to prevent bridge formation and therefore any pebble flow blockages. The design may allow the fuel to be recycled many times through the core to flatten the radially-averaged axial burnup and power profile while also increasing the average discharge fuel burnup (due to less leakage). The flatter axial power profile also reduces the maximum accident temperatures (Geringer and Reitsma, 2010) since the decay heat axial production profile is also flatter allowing a more evenly conduction and radiation to the vessel and outside cooling panels. This loading and unloading of the fuel spheres are performed on-line at full power operation conditions facilitated by a fuel handling system (see Fig. 2 right). The main functions of the fuel handling system are listed in the figure.

The burnup of the fuel is measured after it has been extracted from the core, and based on the measured value, the fuel is either returned to the core to pass through once more or if a target burnup has been reached, it is discharged as spent fuel. The huge advantage of on-line refueling is the increase in the plant availability since no refueling outages is required. The fuel circulation rate and discharge burnup is a function of the average number of passes and fuel enrichment, and may need adjusted to ensure the core remains critical with the desired excess reactivity. With on-line refueling the excess reactivity throughout the lifetime of the reactor can be limited to just overcome operational transients due to power changes (xenon buildup).

Figures and Captions

Fig. 1 View of a pebble bed gas cooled reactor with TRISO particle fuel contained in 60 mm diameter graphite spheres (Pebbles). For electricity generation a direct helium power conversion cycle (Brayton) or an indirect steam cycle (Rankine) has been studied. The Brayton cycle leads to increase efficiencies ($\sim 50\%$) if the outlet gas temperature is increased (up to 900°C typically) while for the Rankine cycle ($\sim 41\%$) gas outlet temperature (typically 750°C) is dictated by the ideal steam conditions ($\sim 540^\circ\text{C}$) based on conventional steam power turbines. Simplified system diagrams (Reitsma, 2010) are included in Fig. 3. Many alternatives and combinations of cycles are possible that may use intermediate heat exchangers (IHX) or heat storage to do co-generation (electricity and heat) or to deliver process heat at multiple temperatures.

In Table 1 the typical core parameters and maximum thermal power outputs for pebble bed gas cooled reactors are given for these two power conversion cycles. The study ensures compliance to the modular design approach and specifically the maximum fuel temperatures (1600°C was used) in accident conditions (Said et al., 2006).

The majority of pebble bed designs actively being pursued today has a cylindrical core shape and is making use of the indirect steam cycle. The typical layout and features of the reactor and nuclear steam supply system is shown in Fig. 4 (derived from Reitsma, 2010). The pebble bed core and graphite reflectors are shown. The control rods drive mechanism and secondary shutdown storage-and release systems are situated above the core and will insert control rods or release small absorber spheres into holes in the side reflector graphite blocks. This prevents damage to the fuel spheres (no insertion into the pebble bed) but also limit core diameter to ensure adequate shutdown. The fuel spheres are unloaded through a central defuel chute and can be reloaded to the top of the pebble bed. This is all contained within the reactor pressure vessel (RPV). The positioning of the control rod drives within the RPV exclude control rod ejection as a postulated accident in this example.

The reactor is coupled via a cross vessel duct to the steam generator and helium blower. The RPV, cross connecting vessel and steam generator vessel contain the helium coolant typically pressured between 4 and 9 MPa. The helium coolant is circulated in the outer volume of the cross duct, through the bottom reflector, up in the side reflector and then downwards through the pebble bed. The hot gas is collected below the core in the hot gas plenum and returned to the steam generator through the inner hot gas pipe where it flows downwards on the outside of the steam generator tubes returning on the inner boundary of the steam generator vessel

Fig. 2 Fuel sphere load and multi-pass concept (left) and fuel handling system (on the right).

to the circulator. The steam generator is positioned below the active core height to limit water and steam ingress in the case of a tube leak or rupture. The water enters the steam generator from below with the steam line exiting at the top, feeding the steam power turbine.

Operations

The pebble bed gas cooled SMR has several characteristics that enhances its safety but specifically also simplify operations, since margins are large and the response typically slow. The heat transfer fluid used is helium, an inert compressible gas with no phase change (no sudden changes in heat removal) and excellent heat transfer properties. The large helium temperatures difference across the core ($\Delta T = T_{\text{outlet}} - T_{\text{inlet}}$) requires a smaller coolant mass flow resulting in smaller pumping power needs. The large amount of graphite used as moderator, reflector and core structural material has a large thermal capacitance that, combined with the low power density, result in very slow temperature transients. This simplify the control system and allows for time before any operator actions are needed. Although these salient features suggest ease of operation with much simpler control and operator actions, it is better to rather look at actual experience.

The AVR 15MWe operated for 21 years till 1988. It achieved a high average availability factor of 66.4% over its operational life, even though it was used as a test reactor to perform bulk tests of different fuel types (Hittner, 2019), and used to do many safety demonstrations. It achieved a maximum availability factor of 92% in 1976 (Baumer et al., 1990). These are exceptionally high values for that time. The irradiation dose to personnel was very low (compared to the levels at other plants at that time), and the plant demonstrated it flexibility and robustness running on different fuel (HEU-Thorium, LEU, etc.), surviving oil and water ingress accidents, and performing many safety demonstrations. "Operation of the plant presents no problems and makes no high demands on the operating personnel. All the faults which occurred could essentially be eliminated with our own plant crew" (Baumer et al., 1990). Now under decommissioning, the plant also contributes towards the future knowledge needed in this area.

The THTR 300 operated for only 4 years (Hittner, 2019). It was built before the modular HTGR principles were generally accepted and had, for example, a relatively higher power density at 6 MW/m^3 (compared to the HTR-Modul value of 3 MW/m^3), made use of 42 absorber rods directly driven into the pebble bed core, and used a large pre-stressed concrete reactor pressure vessel (PCRV). It therefore required active cooling to remove the decay heat. It had good operational behavior and low activity in the primary circuit, but some failures and operational difficulties contributed to the lessons learned for modern pebble bed reactors. Many of the fuel spheres ($\sim 1.2\%$) were damaged due to core control rod insertions into the pebble-bed in the core. The on-line defueling could not operate at full power (due to back pressure design issues) and this required operation at reduced power and flow that negatively impacted on the capacity factor. The best availability factor of 61.7% was achieved in 1987.

Fig. 3 Simplified power conversion system diagrams for indirect steam cycle (Rankine upper) and direct helium cycle (Brayton lower) with low and high pressure compressors (LPC and HPC). Reitsma F (2010) Presentation made at the PHYSOR 2010 Workshop on “Reactor Physics and Design of Next Build Reactors” - The Pebble Bed Modular Reactor: From V.S.O.P. (Very Superior Old Product) to Generation-IV candidate. 14 May 2010.

In general, the operating experience from the German prototypes has confirmed the good behavior of coated particle fuel under irradiation with very low release of fission products into the coolant gas (Gerczak, 2021). It has also confirmed “easy control, high thermal inertia and significant operating safety margins” (Kugeler and Zhang, 2019).

The HTR-10 pebble bed test reactor in China reached first criticality in December 2000, and by January 2003, after steady increase from initial 30% operations, reached the full 100% rated power and 700 °C outlet temperature, and then sustained

Table 1 Typical conditions and maximum power output for modular pebble bed gas cooled reactors.

Design	Cylindrical		Annular	
Core height [m]	11.0		11.0	
Inner core diameter [m]	–		2.0	
Outer core diameter [m]	3.0		3.7	
RPV outer diameter [m]	5.7		6.4	
Variant	Brayton	Rankine	Brayton	Rankine
Inlet temperature [°C]	500	250	500	250
Outlet temperature [°C]	900	750	900	750

Mean power density [MW/m ³]	2.83	3.21	5.07	5.54
Helium mass flow rate [kg/s]	105.9	96.24	204.5	178.6
Pressure-drop over the core [bar]	1.27	0.84	3.55	2.16

From Said NB, Lohnert G, Buck M, and Bernnat W (2006) The impact of design on the decay heat removal capabilities of a modular pebble bed HTR, *Nuclear Engineering and Design* 236: 648–656.

72 h of full power operation satisfying the technical specifications and design requirements. Many planned commissioning tests have been performed to test the fuel while several tests were conducted to demonstrate the passive safety characteristics. “For the future INET first plans to raise the outlet temperature to 750°C in the HTR-10 core with the same sphere fuels and to replace the steam generator with a gas turbine power conversion unit. The new designed reactor is named HTR-10GT” (Lang et al., 2017). More operational lessons learned has been summarized by (Beck and Pincock, 2011).

In Table 2 the main operating conditions of the three pebble bed reactors that was built and some of the leading pebble bed SMR designs are summarized in Table 2 (Baumer et al., 1990; IAEA, 2017; Hittner, 2019; IAEA, 2020). It should be pointed out operational experience are only for indirect steam cycles with no experience with helium gas turbine direct cycles.

The high-temperature gas-cooled reactor pebble-bed module (HTR-PM) demonstration power plant (Zhang et al., 2016) at the Shidao Bay site in Rongcheng, Shandong Province, China, has completed cold commissioning of both units in the last quarter of 2020 (World Nuclear News, 2020). First criticality and power operations are expected in 2021. Even though the same ‘easy and non-demanding’ behavior of the AVR is expected, a positive operational experience will be invaluable to the prospects of pebble bed gas cooled reactor deployment.

Safety characteristics

The safety philosophy and characteristics of modular HTGRs is well documented and apply to both pebble bed and prismatic designs. It is very well summarized by (Ball, 2014): “No fuel failure for loss of coolant flow and coolant accidents, or for all foreseeable reactivity events, even with no corrective actions.”

Within the framework of an IAEA coordinated research project on Modular HTGR safety design, Reitsma et al. (2016) made a detailed review of all the safety characteristics of HTGRs summarized here. Some of these characteristics were already mentioned such as the use of an inert single-phase helium gas and the slow thermal transients due to the large mass (heat capacity) of graphite. Other favorable inherent safety characteristics includes the use of high quality ceramic coated particle fuel and the strong negative reactivity coefficients.

Most of the other favorable safety features are obtained by the correct design choices mostly to ensure no core meltdown or significant radionuclide release are possible even in the event of depressurization of the helium coolant and loss of all active forced convection cooling systems. This can only be achieved by selecting a low power density and relying on natural means only to transport the decay heat away from the fuel, i.e. by radiation, conduction and the natural convection outside the RPV. To ensure a relatively large heat rejection surface area a long slender core and uninsulated RPV are typically used. The heat is removed to cooling panels outside the reactor and the building structures and surrounding earth can serve as the ultimate heat sink if the system fails. During loss of active cooling transients, the maximum fuel temperature must remain below levels (~1600 – 1800 °C or even higher, EPRI, 2020) where significant fuel damage may occur with some margin. It is also important to note that only a very small fraction of the fuel (typically < 5%) will be at these high temperatures, while the rest of the fuel is substantially cooler (a significant fraction may be lower than the normal peak operating temperatures).

The critical element of HTGR safety is the TRISO (TRi-structural ISOtropic) coated particle (CP) fuel. It is capable to contain almost all fission products for the expected operating and postulated accident temperatures (Gerczak, 2021). The core design must ensure sufficient margins in the operating and accident conditions to prevent damage to the fuel. The most important of these conditions is the maximum accident temperatures that, together with the other conditions, being the fuel operating temperatures, fast fluence, burnup and maximum power density, must be bounded by the fuel design and test envelope (EPRI, 2020). No large early release (~first 24 h) of fission products due to coated particle failure is therefore possible (not a credible scenario).

Fig. 4 Typical layout of the reactor and nuclear steam supply system (Rankine cycle) for a pebble bed gas cooled reactor. Redrawn based on the HTR-Module Reitsma F (2010) Presentation made at the PHYSOR 2010 Workshop on “Reactor Physics and Design of Next Build Reactors” - The Pebble Bed Modular Reactor: From V.S.O.P. (Very Superior Old Product) to Generation-IV candidate. 14 May 2010.

In the worst-case scenario with the loss of all the coolant (and therefore no active cooling) the core will heat up and reach a maximum typically between 1–3 days after the accident and then starts cooling down. The increased fuel temperatures will cause the release of some additional fission products through increased diffusion through the TRISO coatings even if no additional failures occur. This may contribute to an increased radionuclide to the environment, called the delayed release. The modular HTR design ensures that these values remain far below the regulatory limits.

A HTGR core contains billions of coated particles and the failure mechanisms of CP fuel are decoupled and totally independent. When CP failures occur, they have been shown to develop after a long time (hours and days) at very high accident temperatures. In the German HTR fuel irradiation program over several decades no additional coated particle failures were found due to accident temperatures of up to 1600 °C (IAEA, 2010). The expected failure rate can only be expressed as a statistical probability dependent on the burnup, temperature and time at temperature. The failure of one coated particle cannot lead to the failure of a neighboring CP. A CP failure also has no effect on the cooling of the fuel as a failure will not change the heat removal path. The amount of fission

Table 2 Main operating conditions of pebble bed gas cooled reactors and designs.

Design	Power [MW _{th}]	Power [MW _e]	Power density [MW/m ³]	Inlet/outlet temperature [°C]	Helium pressure [bar]	# Of fuel spheres	²³⁵ U enriched [%]	Cycle

products that can potentially be released when a failure occurs is very small, and many CP will need to fail to be of any consequence. The fuel failures exhibit no cliff edge effects.

The large negative temperature coefficient (and large fuel temperature margins) implies that the Doppler, or fuel temperature reactivity coefficient, acts promptly thus stabilizing the nuclear chain reaction. The on-line refueling in the pebble bed reactor also ensures very small excess reactivity at any given time.

The HTGR designs must guard against water ingress due to steam generator tube leaks or ruptures that can cause reactivity excursions and limited graphite corrosion and fission product release (washout of damaged CP). In such conditions, a standard scram and isolation of the reactor from the steam generator is performed. The prevention of massive air ingress and its corrosion effect on graphite and fuel above 400 °C has also been studied and found to be a very low probability event, and design and operational measures are included to mitigate it.

Areas of application

The pebble bed gas cooled SMRs as part of HTGRs were always envisaged for both electricity generation and process heat applications. The higher outlet temperatures of pebble bed reactors already lead to higher efficiencies (~41%) compared to water cooled reactors (~34%) and match the efficiencies of conventional fossil fueled power plants (for more details see [Pioro et al., 2021](#)). As explained above the use of direct cycle gas turbines can increase this substantially (~50%). The electricity market is only about 18% of the total energy market with the rest used for heat and transportation. HTGRs are ideally suited to make a carbon free contribution to all these energy markets ([Bragg-Sitton and Boardman, 2021](#)).

Due to the high outlet temperatures HTGRs can match the range of temperatures required for process heat applications in most industries or to produce synthetic fuels to replace gasoline, diesel and kerosene for transportation in a carbon dioxide neutral way. In the International Atomic Energy Agency report on Industrial applications of nuclear energy ([IAEA, 2017](#)) as well as in ([Bragg-Sitton and Boardman, 2021](#)) a comprehensive summary of all these potential markets is provided with HTGRs and pebble bed reactors specifically referenced.

The AVR reactor ([Baumer et al., 1990](#)) operated at outlet gas temperatures of 950 °C through most of its operating life demonstrated the potential for pebble bed gas cooled reactors to deliver high temperature heat for industrial processes and hydrogen production. In fact, the melt-wire gas temperature measurements above the core and helium core bypass studies have shown that the average gas temperatures above the pebble bed was probably as high as ~1136 °C and even higher maximum temperatures ([Viljoen et al., 2008](#)). This shows the potential of the fuel and core structures to tolerate even higher operating temperatures in the future, although many other aspects still need to be developed and tested. Additional information is provided in [Fütterer et al. \(2021\)](#).

Development status

A summary of the main pebble bed designs is given in [Table 3](#). More details on each of the designs can be found in the 2020 edition of *Advances in Small Modular Reactor Technology Developments* ([IAEA, 2020](#)).

Most of these designs closely follow the modular principles established with the HTR-Module design ([Reutler and Lohnert, 1984](#)). The PBMR400 design propose an annular core and direct cycle while the rest are all cylindrical configurations and use

Table 3 Summary of pebble bed gas cooled reactor designs.

<i>Design</i>	<i>Developer</i>	<i>Development status</i>
HTR-10 (10 MW _{th})	Tsinghua University, China	Test reactor in operation since 2000
HTR-PM (2 × 250 MW _{th})	Tsinghua University, China	Under commissioning. Commercial demonstration in 2021
Xe-100 (200 MW _{th})	X Energy, LLC, United States of America	Basic design development under way
HTMR-100 (100 MW _{th})	Steenkampskraal Thorium Ltd., South Africa	Concept design
AHTR-100 (100 MW _{th})	Eskom Holdings SOC Ltd., South Africa	Concept design completed; R&D work on hold since 2019
PBMR-400 (400 MW _{th})	Pebble Bed Modular Reactor SOC Ltd., South Africa	Preliminary design completed; test facilities demonstration; project stopped in 2010
RDE (10 MW _{th})	National Nuclear Energy Agency (BATAN), Indonesia	Detail design development is in progress
HTR-Module (200 MW _{th})	Interatom/Siemens in Germany	The reference / first modular pebble bed design developed in the 1980s and never constructed

indirect cycles (Matzner, 2004). Two designers propose a once-through fuel management system (AHTR-100 and HTMR100) while the others propose a multi pass fuel management scheme (average number of passes between 6 and 15). The HTR-PM is already under commissioning (World Nuclear News, 2020) and will be the first Generation-IV SMR to operate in the world. It is expected to increase confidence in the pebble bed SMR technology and encourage many countries to proceed with planned HTGR activities. Development of the Xe-100 is also progressing well and engagement with the US regulator and start of construction is foreseen in the next few years (IAEA, 2020).

Further insight into the different historical reasons why pebble bed gas cooled reactors (and more generally HTGRs) were not further developed and commercialized can be found in Fütterer et al. (2021).

Objectives of ongoing development work

In the near term the goal is full-scale demonstration and commercialization of pebble bed gas cooled SMRs based on the HTR-PM commissioning and operational feedback. Despite past experience and high technology readiness levels many of the suppliers that were available in the 1980s and 1990s are no longer available, and a new supply chain is needed. For the HTR-PM all major systems and components were manufactured in China. Many test facilities were also built to perform full-scale engineering verification experiments at hot conditions in a helium environment. This includes the main helium blower, steam generator module, the fuel-handling and spent fuel storage systems, control and shutdown systems and the helium purification system (Zhang et al., 2016). These experiments exposed and solved many engineering technical problems.

Almost all the designs presented in Table 3 are based on known technology and systems with a relatively high technology readiness level that had been demonstrated before or in the HTR-PM project. However, the PBMR400 makes use of a direct cycle for which a helium turbine is required. When the project was executed in the 2000s this represented a huge challenge, and substantial development costs were incurred. No such large (400 MW_{th}) helium turbine has been built before and the high temperature (900 °C) presented material challenges. The proposed blade cooling solutions represent a direct cold helium bypass and thus a substantial loss of efficiency. New materials are needed to be qualified if the direct cycle is to be a viable option.

The niche market for pebble bed gas cooled SMRs must surely be cogeneration and the process heat market. Many market studies have been performed to look at hybrid energy systems or integration with existing industrial complexes to provide steam and electricity. Hydrogen production is also increasing in importance and several demonstration plants are under development. The development of innovative intermediate heat exchangers (IHX), especially of compact printed circuit designs, has been studied in the past for hydrogen production, but is also important for cogeneration and thermal storage (with different coolant options such as helium-helium, or helium-molten salt). The developments using existing materials are being carried out while new materials are under development for the future.

The AHTR-100 design is really a VHTR design with outlet helium temperature of 1200 °C. It also introduces novel power conversion concepts that include a direct cycle, thermal storage and bottom indirect cycle, that would require further research and development. The use of a concrete reactor vessel also requires new innovative decay heat removal such as the use of a passive heat pipe system that needs additional R&D.

Major challenges and R&D needs

Licensing is often singled out as one of the main challenges to deployment new advanced reactors. However, pebble bed gas cooled reactors have been licensed and operated before, so what has changed? “The answer is two-fold: In the last 30 years the safety and licensing requirements have been strengthened substantially but in the process it also became more light water reactors (LWR) technology specific with the consequence that it is more difficult to interpret and apply to HTGRs. The second is the change in the safety philosophy used in all modern HTGR designs where many of the safety systems required in LWRs are made obsolete” (Reitsma,

2017). It is possible to license pebble bed reactors under LWR requirements and licensing approach. This was the case in Germany before and recently again with the HTR-PM in China. However, in both cases agreement has been reached before license applications were made on specific exceptions and additions to the requirements and approach.

In recent years excellent progress has been made with the development of advanced non-water cooled reactor licensing. For example, the US NRC published RG 1.232 (NRC, 2018) that not only attempt to make requirements technology neutral, but also includes a specific appendix on Modular High-Temperature Gas-Cooled Reactor Design Criteria. Similar efforts have been made by regulators around the world that should enable the appropriate focus in licensing HTGRs.

The licensing of pebble bed reactors to be used for cogeneration and directly coupled to industrial processes for process heat applications may present a specific challenge. Potential transients and external hazards must be included in the design considerations of both the nuclear and industrial plant, or innovative decoupling systems needs to be applied. Studies on safety, technology and economics are being performed.

The research and development need for pebble bed reactors (VHTRs) are well summarized in the R&D Outlook for Generation IV Nuclear Energy Systems (GIF, 2018). The TRISO fuel technology was successfully reestablished to produce excellent fuel quality both in China (Freis et al., 2020) and the USA (EPRI, 2020). The fuel test envelope has been expanded in burnup, power density, neutron fluence, irradiation temperatures and accident temperatures. R&D in the future may look at expanding this test envelope further by investigating alternative coatings and matrix materials.

Development for higher temperature applications require new materials and instrumentation. High temperature metals will allow new designs of vessels, pipes, valves, gas turbines and IHX that can withstand the higher operating and accident conditions. R&D on improved graphite grades is expected to result in better mechanical and thermal properties at higher temperatures and fluences while showing better resistance to air and water ingress. Ceramics and composite materials for control rod cladding or in-core structural materials are also needed.

Finally, R&D on improved software codes and simulation methods are continuing to reduce uncertainties and improve the verification and validation status of these codes through benchmarking and comparisons with experiments and plant data.

Introduction

Since the earliest days of nuclear reactor development, small reactors – generally considered reactors with power less than 300 MWe – have seen wide application. A principal reason for this is the fact that initial development and demonstration of new reactor technologies generally start with small scale demonstration reactors that can form the basis for larger implementations of the particular reactor type. Additionally, there are many special applications – aside from large scale grid electricity production – in which small systems are most appropriate. These include reactors designed for scientific research and testing, reactors for power supply in remote or isolated locations, reactors for training and radioisotope production, and reactors for ship propulsion. For purposes of electricity production, there has long been a trend toward larger plant sizes to achieve economy of scale since nuclear plants are very capital-intensive systems. However, in recent years there has been progressively increasing interest in the development of small modular systems to address a different set of objectives including modularity, transportability, factory fabrication, passive safety and decentralization/localization of power generation facilities – hence the growing interest in Small Modular Reactors, or SMRs (Smith, 2009).

One of the most important defining characteristics of a reactor technology is the mechanism chosen for heat removal and reactor cooling; a wide variety of coolants have been considered including gases such as helium or carbon dioxide; liquids such as water, heavy water, molten salt, sodium and potassium; and the heavy liquid metals mercury, tin, lead and the eutectic alloy of lead and bismuth known by its acronym LBE. Additionally, technologies such as heat pipes can be used for heat removal without relying on the circulation of bulk coolant fluids.

Another defining reactor technology characteristic is the neutron energy spectrum of the reactor. The two most prominent options are reactors operating at thermal neutron energies (centered around ~ 0.1 eV) and those operating with neutrons in the fast-energy range (i.e., from ~ 100 keV to greater than 1 MeV). Coolants and other reactor materials (e.g., moderators) containing high concentrations of light elements (e.g., hydrogen in water or carbon in graphite) are effective in slowing down fission neutrons to thermal energies, and therefore are favored for thermal reactors. On the other hand, coolants and other reactor components in which materials comprised of light elements are minimized in favor of those containing heavy elements are used for fast reactors. Liquid metals are a category of such materials, and heavy liquid metals (HLMs), in particular, can be highly effective as coolants for fast spectrum reactors. Advantages associated with fast spectrum reactors include the following:

- Greatly enhanced fuel utilization.
- Toxicity reduction of spent fuel and waste.
- Safety advantages since fast reactors can operate at low pressure with large thermal inertia and negative power and temperature coefficients of reactivity (IAEA, 2006).
- Potential dramatic extension of fuel lifetime and reduction of refueling requirements.

The last of these advantages, enabled by the ability to breed and burn fuel constituents, is of particular importance to many HLM-cooled fast SMR concepts which have fuel designs that in some cases result in core lifetimes of up to 30 years and can therefore operate for such a period without the need for refueling.

This chapter focuses on the topic of HLM-cooled fast SMRs.

History

The first operational nuclear reactor was the graphite-moderated thermal reactor known as Chicago Pile-1 (CP-1) which reached first criticality on December 2, 1942 as part of the wartime Manhattan Project. Following the end of World War II, there was a great deal of exploratory research on reactor technologies, and as part of that effort, the first fast spectrum reactor – known as Clementine – was developed (LANL, 1993; LANL, 2018). Clementine, first operated in 1946 at Los Alamos National Laboratory, was not only the first

fast reactor; it was also the first reactor fueled by Plutonium, and it was the first reactor cooled by a HLM (mercury). At 25 kW power, it can be considered the first HLM-cooled fast SMR.

Mercury had been chosen for Clementine in order to provide a coolant that would sustain the desired fast neutron spectrum, but also because it is a liquid at room temperature and would therefore avoid the engineering difficulties of other metal coolants that would need to be maintained above their melting temperature for operational and safety reasons. However, it was found that mercury as a coolant also had several disadvantages including its toxicity, relatively high vapor pressure, relatively low boiling temperature and, perhaps most important, its high neutron absorption cross sections. As a result, following the Clementine reactor experience, mercury was not seriously considered for future development.

On the other hand, lead and its alloy with bismuth LBE¹ were found to have very favorable characteristics for use as coolants in fast spectrum reactors. During the Cold War, the US and the Soviet Union each explored reactor technologies for submarine and surface ship propulsion. While the US declined to pursue HLM coolant technologies due to concerns over corrosion and material compatibility, the Soviet Union (and subsequently Russia) embarked on a substantial development program that ultimately resulted in the production of a fleet of high-performance “Alfa Class” submarines powered by reactors cooled by LBE. Fig. 1 is a photo of the Alfa Class submarine (National Archives, 1983). Said to be the world’s fastest and deepest diving submarine of its time (Military Today, n.d.), a total of 15 reactor cores were built and operated in support of 8 submarines and 2 onshore reactors. In all, ~80 reactor-years of operating experience were accumulated and led to continued Russian interest and technology leadership with regard to HLM-cooled reactors following the dissolution of the Soviet Union.

More recently, interest in HLM-cooled reactor technology has grown significantly with national and industrial initiatives around the world. Current activities, ranging from early pre-conceptual design and analysis to final design, site preparation and construction are taking place in many parts of the world with activities under the Generation IV International Forum (GIF) in Russia, the United States, the European Union, China, Japan and Korea (Alemberiti et al., 2017; Alemberiti, 2021).

In the late 1990s, an effort was initiated by Lawrence Livermore National Laboratory (LLNL) to organize a consortium of US national laboratories, universities and industry to explore SMR concepts that would exhibit characteristics most suitable for small, transportable and highly proliferation-resistant nuclear power systems capable of meeting the growing power demands of many regions of the developing world. The initiative originated the acronym STAR standing for Secure Transportable Autonomous Reactor (Brown et al., 1999). Multiple small reactor concepts were considered, including those cooled by a full range of different coolants - gas, liquid metal, light water and molten salt. Among the most promising concepts resulting from this initiative were HLM-cooled fast reactor systems. Two worth noting in particular are reactor concepts known as the Encapsulated Nuclear Heat Source (ENHS) (Greenspan et al., 2008; Greenspan, 2003; Wade et al., 2002) and the Small Secure Transportable Autonomous Reactor (SSTAR) (Smith et al., 2008).

The ENHS concept envisioned a reactor that achieved the STAR objectives of small size, transportability and high degree of proliferation resistance by implementing a sealed module in which there were no penetrations to provide paths for coolant flow out of or returning to the module. Instead, the sealed module contained all the active reactor components and primary LBE coolant which served to remove the heat from the core by natural circulation. Heat would be transferred to an external secondary-coolant pool by passive, through-the-wall conduction.

The SSTAR concept was similarly based on the achievement of the STAR objectives – proliferation security through the sealed nature of the reactor vessel, very long core life, transportability by virtue of its physical dimensions and capability of autonomous operations, and passive safety through simplicity of design. It should also be noted that a follow-on concept – known as SuperSTAR was subsequently proposed. Details on SuperSTAR can be found at (ANL, 2012 and Sienicki et al., 2011).

Both ENHS and SSTAR are discussed further in “Section Current/recent HLM fast SMR technology developments” of this chapter.

Fig. 1 Alfa class submarine. From National Archives (1983) A Port View of a Soviet Alfa Class Submarine. National Archives Identifier 6383596. Available at <https://catalog.archives.gov/id/6383596>.

¹Note that LBE is the eutectic alloy of bismuth and lead, namely 55.5 wt% bismuth and 44.5 wt% lead (OECD-NEA, 2015).

More recently, a number of HLM-cooled SMR concepts have been conceptualized and are in varying stages of development. These additional concepts are also described further in “Section [Current/recent HLM fast SMR technology developments](#)” of this Chapter.

Heavy liquid metal coolants

Heavy liquid metals have been explored as primary coolants for fast nuclear reactors since the early days of reactor technology development primarily because they can effectively remove heat from reactor cores without appreciably degrading the energy spectrum of the neutrons in the reactor. Candidates that have been considered at various times include tin, mercury, lead and LBE. While mercury was the coolant used in the first fast reactor Clementine, its properties, including toxicity, vapor pressure and high tendency for neutron absorption, resulted in disfavor for concepts developed after this first application. Another heavy liquid metal, tin, has also been considered ([Weeks, 1971](#); [Can, 2006](#)) but, due to its high corrosivity and other factors, has not to date been significantly developed or incorporated into design concepts for HLM-cooled reactor systems.

The two remaining potential coolants, lead and LBE, are the principal HLM coolants being actively incorporated into small fast reactor concepts. While the fundamental characteristics of these coolants are well described in technical detail elsewhere ([OECD-NEA, 2015](#); [Cinotti et al., 2010](#); [Smith and Cinotti, 2016](#)), an overview of some of the advantages and disadvantages of each is provided in the following paragraphs.

Lead and LBE coolants are highly suitable for fast reactor applications due to properties they share, namely:

- The high atomic masses of lead (~ 207 g/mol) and bismuth (~ 208 g/mol) ([OECD-NEA, 2015](#)) ensure that the fast neutron energy spectrum characteristic of fission neutrons will not be excessively degraded due to neutron scattering interactions with these coolant materials despite the non-negligible level of inelastic scattering in these coolants.
- The very high boiling points of lead (1737°C) and LBE (1630°C) ([OECD-NEA, 2015](#)) make coolant boiling extremely unlikely under any conceivable condition, and these very high temperature margins contribute to the safety and design simplification potential for HLM-cooled systems; in addition, the problem of void formation in the primary circuit from coolant vaporization is virtually eliminated.
- Lead and LBE coolants have relatively benign chemical properties such that they present no rapid chemical reactions with either water or air. This is an important factor in contrast to other liquid metal fast reactors (i.e., sodium cooled systems) which must introduce complex and expensive measures to ensure that the radioactive and chemically energetic primary coolant is reliably isolated from contact with water and air.
- The low saturation vapor pressures of both lead and LBE (about 1×10^{-2} Pa at 800 K or 527°C , ([OECD-NEA, 2015](#))) enable operation of the systems at or very close to atmospheric pressure.
- Lead and LBE exhibit the ability to retain radionuclides, including volatile species such as iodine and cesium, should a fuel failure occur
- As heavy elements, lead and LBE provide inherent shielding of gamma radiation from fission products
- They exhibit favorable neutronic properties, including ([OECD-NEA, 2015](#)):
 - small (fast) capture cross-sections (for small parasitic loss of neutrons);
 - high scattering cross-sections (for small leakage of neutrons from the core);
 - small energy loss per elastic collision (to limit spectrum softening (moderating) effects)
- The thermodynamic properties of lead and LBE are favorable in enabling passive cooling by natural circulation. HLM-cooled fast SMR concepts generally rely on this natural circulation process for shutdown heat removal, and some concepts are designed to operate without forced circulation during normal operations, relying instead on natural circulation for operational cooling.

Some additional characteristics shared by lead and LBE (and which must be overcome by system engineering, material selection and design) include:

- Both coolants have material compatibility issues ([OECD-NEA, 2015](#)), most importantly the potential for corrosive attack on conventional structural materials. While this corrosion potential is relatively low for temperatures below 450°C , it increases with temperature above this level. Design approaches to address this challenge include careful management of coolant chemistry, especially oxygen concentration; restriction of coolant temperatures to limit maximum temperatures below those that present heightened corrosion rates; and use of materials (alloys, coatings and coolant additives) that provide corrosion resistance.
- Both coolants have melting temperatures that present engineering challenges in that the primary coolant must be maintained above the coolant melting temperature throughout the primary system to avoid freezing and the potential for flow blockage or other undesirable impacts. The melting points for lead and LBE are 327°C and 125°C , respectively ([OECD-NEA, 2015](#)). In both cases, this presents engineering and operational constraints; however, this is clearly a greater challenge for lead as a coolant.
- The activation of these coolants in a neutron flux creates undesired radioactive activation products that must be addressed, and the formation of polonium-210 is undoubtedly the contaminant of greatest concern due to its very high radiotoxicity and volatility and its contribution to heat generation within the coolant itself in the case of LBE as a coolant; issues related to generation of polonium-210 represent much greater challenges for LBE as a reactor coolant.

These considerations are central to the choice of lead- versus LBE-cooled reactor designs. The elevated melting temperature of lead in comparison to LBE creates engineering design challenges and also constrains the operational temperature cycle of the primary circuit for lead-cooled systems. On the other hand, the production of polonium-210 as a coolant activation product is primarily a challenge for LBE-cooled systems due to the presence of bismuth in the alloy mixture and the reaction:

Although polonium-210 is also formed in lead, the rate of formation is extremely small whereas in an LBE-cooled reactor, the formation and equilibrium level is greater by nearly 4 orders of magnitude (Can, 2006). Note that polonium-210 decays with a half-life of 138.4 days into lead-206 by an α emission of 5.3 MeV. As a result, polonium-210 represents a substantial heat load in the coolant as well as being highly radiotoxic in the event of release. The polonium production in an LBE-cooled reactor is so high that in an 80 MWe, LBE-cooled accelerator-driven subcritical reactor developed in Europe, the equilibrium polonium inventory was calculated to be 2 kg and represented a decay heat in the coolant that, 5 days after a shutdown, would equal the decay heat power of the fuel itself (Cinotti et al., 2011). As a result, LBE-cooled reactor concepts must incorporate systems, design features and/or operational constraints to address both the toxicological and heat-generation issues related to accumulation of polonium-210.

In comparing lead and LBE as coolants for prospective fast SMR concepts, the balancing between advantages and disadvantages of each have led to the current situation in which both coolant types are well represented in concepts under current development. This is true for HLM-cooled systems of different sizes, including small and very small reactors.

Current/recent HLM fast SMR technology developments

While HLM-cooled small fast reactors have been considered for development since early in the era of nuclear technology (e.g., Clementine in the 1940s (LANL, 2018) and Soviet/Russian reactors for the Alfa class submarine beginning in the 1950s (Military Today, n.d.)), in recent years interest in this technology has rapidly expanded. Current developments now are represented by design and development activities throughout the world and especially in the Russian Federation, the European Union, China, the US, the Republic of Korea and Japan, each of which are members of the Generation IV International Forum (GIF) provisional System Steering Committee for the lead-cooled Fast Reactor (LFR) – see Stanculescu (2021) and Alemberti (2021). Some of these key recent and ongoing developments are summarized in this section.

Note that while the small reactor categorization is generally defined in terms of power (up to 300 MWe), three separate types may fall into this definition. The first type is the category of small, special purpose reactors intended for training, laboratory experimentation and/or radioisotope production. The second type, representing the majority of systems discussed in this section, includes reactors designed for operation in the SMR power range as low as a few MWe and up to 300 MWe. The third type is represented by demonstration reactors that are purposely designed and operated in this lower power range but as prototypes for larger follow-on designs that would not be considered to be in the SMR category. Each of these types is represented in the summaries that follow. Table 1 summarizes the systems discussed in this section.

SVBR-100

The logical follow-on to the experience gained in the development and operation of the Soviet/Russian Alfa-class submarine reactors is the SVBR-100 (Petrochenko, 2011; Zrodnikov et al., 2011). The project is being implemented by a joint venture between the Russian state corporation Rosatom and the private energy company Irkutskenergo - AKME-Engineering Joint Stock Company (AKME). The SVBR-100 is an LBE-cooled reactor with a power rating of 100 MWe. By the end of 2014, most of the capital-intensive and high risk stages of research and design work had been completed, a license for placement (siting) was obtained (2015) and the project moved to the stage of licensing and preparation for construction of a first-of-a-kind demonstration reactor

Table 1 Summary of recent and current HLM-cooled fast SMR concepts.

Country/sponsor	Reactor	HLM Coolant	Power, MWe	Type	Current Status
Russian Federation	SVBR-100	LBE	100	SMR by design	Licensed for placement (siting); continuing development
	BREST-OD-300	Lead	300	Demonstrator	Final Design, Licensed for construction
European Union	ALFRED	Lead	125	Demonstrator	Conceptual design
	SEALER	Lead	3–10	SMR by design	Conceptual design
China	CLEAR-M	Lead	10	Experimental	Pre-conceptual
United States	ENHS	LBE	47/68	SMR by design	Discontinued Development
	SSTAR	Lead	20	SMR by design	Discontinued Development
US-Europe	Hydromine LFR-AS-200	Lead	200	SMR by design	Conceptual design
	Hydromine LFR-TL-X	Lead	3–40	SMR by design	Conceptual design
Korea	Micro-URANUS	LBE	20	SMR by design	Conceptual design

in Dimitrovgrad of the Ulyanovsk region of Russia. (Petrochenko et al., 2017) In preparation for construction and operation of the demonstration plant, work is underway to analyze IAEA safety requirements, complete required regulatory documents of the Russian Federation, clarify the technical and economic parameters of the project, and optimize design solutions for a follow-on serialization of the SVBR-100. A description of SVBR-100 demonstrates that this concept is closely aligned with and benefits from the prior development and operational experience gained from the Soviet/Russian submarine propulsion HLM reactor program. **Table 2** provides an overview of selected technical parameters of the SVBR-100 reactor.

The SVBR-100 is designed for use in remote, isolated, or coastal locations, or for dedicated industrial applications. It also envisioned the ability to provide a variety of different outputs such as electricity, process heat, or desalination. (Smith and Cinotti, 2016) **Fig. 2** provides a sketch of the SVBR-100.

BREST-OD-300

The BREST-OD-300 is a 300 MWe demonstration reactor cooled by lead intended as a prototype for future larger-scale reactors for the production of electricity to the grid. This system is one of the reference designs adopted by the Generation IV International Forum provisional System Steering Committee for the Lead-cooled Fast Reactor. (Alemberti et al., 2017) **Table 3** provides selected technical parameters of the BREST-OD-300, and **Fig. 3** provides a sketch.

Notable characteristics of the BREST reactor are the use of a multi-layer metal-concrete vessel with integral layout in which the lead coolant and the primary circuit equipment are located inside the vessel – thus eliminating the potential for the loss of coolant accident. The primary circuit is organized using free coolant levels, and since there are no shutoff valves in the primary circuit, coolant circulation cannot be lost. The design provides for a passive emergency cooling system with natural air circulation and heat removal to the atmosphere. The design features a unique hybrid loop-pool concept for coolant circulation. The mixed nitride fuel with its high density and thermal conductivity, enables full replenishment of fuel in the core (core breeding ratio ~ 1.05) and compensation of reactivity for fuel burnup. See also Stanculescu (2021), Alemberti (2021), and Adamov et al. (2020) for additional discussions of this concept.

It is important to note that on February 10, 2021 a construction license was issued for the BREST-OD-300 making it among the first Generation IV reactors to achieve this important milestone (Rostechnadzor, 2021).

ALFRED

ALFRED, the Advanced Lead-cooled Fast Reactor European Demonstrator, is being developed as a demonstration reactor for the purpose of testing and qualifying the design, components and procedures for the larger-scale commercial European Lead-cooled Fast Reactor, or ELFR. ALFRED additionally represents a potential early realization of a LFR-SMR (Frignani et al., 2017). ALFRED features a compact design with an emphasis on removability and replaceability of major components, a simplified coolant circulation design and an inner vessel to enclose the hot coolant pool (Falcon Consortium, 2021). **Table 4** provides some high-level parameters of ALFRED, and **Fig. 4** provides a primary system sketch. See also Alemberti (2021) for expanded discussion of this reactor concept and Falcon Consortium (2021) as an online resource website for ALFRED.

SEALER

SEALER (Swedish Lead-cooled Reactor) is a small lead-cooled nuclear battery-type reactor under development by LeadCold Reactors for commercial power production in off-grid applications, especially in remote towns and mining locations in the Canadian Arctic. The reactor is cooled by lead, and is sized for 3 MWe output for remote community power generation and 10 MWe for mining operations. An additional variation, developed to meet the SMR needs identified for the United Kingdom, would be scaled for an output of 55 MWe. (LeadCold, 2021) **Table 5** provides some high-level parameters of SEALER and **Fig. 5** provides a sketch. See also Wallenius (2021) for expanded discussion of this reactor concept.

CLEAR-M

The China Lead-based Reactor (CLEAR) is an advanced family of nuclear energy systems cooled by lead and LBE proposed and under development by the Institute of Nuclear Energy Safety Technology (INEST)-FDS team which engages in R&D of advanced nuclear systems and applications of nuclear technology. The team has operated since the 1980s, and has been supported by a series national programs and international cooperation projects. The CLEAR initiative has included a variety of new systems, most recently the CLEAR-M lead-cooled SMR system. As an SMR, CLEAR-M is designed to be easy to transport and install, inherently safe and economical due to its long refueling period, among other characteristics. Table 6 provides some high-level parameters of CLEAR-M, and Fig. 6 provides a sketch.

ENHS

The ENHS concept envisioned a reactor vessel that was a sealed module in which there were no penetrations to provide paths for coolant flow out of or returning to the module. Instead, the sealed module contained the reactor core, one central and one peripheral control/safety assembly and the primary LBE coolant which served to remove the heat from the core by natural circulation. This module, in turn, was to be immersed in a pool of HLM (i.e., a secondary LBE coolant pool). The transfer of heat from the primary coolant within the ENHS module to the secondary coolant pool outside the module was by conduction through the specially designed wall of the ENHS module. This characteristic was highly innovative and one of the most unique features of the ENHS

reactor. There are no pipes, valves or pumps in the primary and secondary LBE coolant loops. Natural circulation results in the capability of passive load following and autonomous control while eliminating the potential for loss-of-flow accidents. Over the 20 year life of the core, the small burnup reactivity swing ensures that the reactor reactivity control system would require adjustment only once every few years.

ENHS was designed for passive load following and a very high level of passive safety. Its fuel burnup concept enabled a 20-year period of operation without refueling or fuel shuffling. The ENHS modules were to be fabricated, fueled and welded-sealed in the factory. They would be transported to the power plant site with the fuel embedded in solidified LBE; no on-site refueling or fueling hardware is required. At end of life, the ENHS module would serve as a spent fuel storage cask and, later, as a spent fuel shipping-cask for return to a central fuel cycle facility. The module concept enables an essentially sealed module that would be easy to install and replace, and this provides a unique approach to achieving a very high level of proliferation resistance for the reactor concept and its associated nuclear fuel cycle. One configuration of ENHS featured operational heat removal by natural circulation only (ENHS1), and in another, natural circulation provided for shutdown heat removal while operational cooling used also a lift pump achieved by bubbling cover gas into the LBE as it emerges from the top of the core (ENHS2). **Table 7** provides selected parameters of both configurations of ENHS, and **Figs. 7 and 8** provide descriptive sketches of ENHS1.

SSTAR

The SSTAR (Small Secure Transportable Autonomous Reactor) concept was introduced as a conceptual design in the early 2000s by a consortium of contributors from US National Laboratories, universities and industry led by Lawrence Livermore National Laboratory with Argonne National Laboratory as the primary design organization. The driving objective behind this initiative was the development of a highly proliferation-resistant small reactor system that would be suitable for deployment to remote locations and developing countries throughout the world. SSTAR is a small natural circulation fast reactor of 20 MWe/45 MWth output. The compact active core would be removed by the supplier as a single cassette and replaced by a fresh core. Key characteristics include transportability by virtue of its physical dimensions, capability of autonomous operation, and passive safety through simplicity of design and the characteristics arising from the inherent properties of lead as a coolant. Some of the unique features of the SSTAR design include a very long core life – up to 30 years – to enable the vessel to be sealed and to keep its fuel inaccessible for its full lifetime of operation. Inherent safety was enhanced by design simplifications such as the reliance on natural circulation for operational as well as shutdown heat removal. Efficiency and compactness was supported by the use of a supercritical CO₂ power conversion system (Smith et al., 2008).

The SSTAR concept was developed to a conceptual design level, but further advancement of the system was limited due to lack of funding following the initial design effort. When the Generation IV International Forum provisional System Steering Committee for the Lead-cooled Fast Reactor was organized, the SSTAR concept was chosen as one of the LFR reference systems despite its legacy status. It remains one of the GIF reference systems. Table 8 provides some high-level parameters of SSTAR, and Fig. 9 provides a sketch. See also Smith et al. (2008), Stanculescu (2021), and Alemberti (2021) for further discussion of SSTAR.

Hydromine LFR-AS-200 and LFR-TL-X

The Hydromine LFR-AS-200 is a highly compact and innovative HLM-cooled SMR. The reactor is cooled by lead. Its compact primary system produces more than 1 MWe per cubic meter of primary system volume, a metric about 4 times greater than that of a large sodium-cooled fast reactor (i.e., SuperPhénix), and about 2–3 times greater than current designs of integral pressurized water SMRs.

In the LFR-AS-200, AS stands for Amphora-Shaped, because of the shape of the inner vessel, and 200 refers to the electrical power in MWe (Cinotti et al., 2017). The innovations incorporated into the design exploit the intrinsic properties of the lead coolant and emphasize plant simplification and compactness, while ensuring passive safety.

The LFR-AS-200 is a pool-type fast reactor with six innovative spiral-tube steam generators (STSG), six mechanical pumps, and flag-type control rods. There is no need of in-vessel refueling machinery nor of intermediate loops. Table 9 provides selected parameters of the LFR-AS-200.

A related family of very small reactors (micro reactors) known as the LFR-TL-X series is also under development. This family of reactors capitalizes on many of the same features as the LFR-AS-200, with the main difference being in the number of major components (pumps and steam generators) and their physical arrangement. In this family of microreactors, TL indicates the characteristics of transportability and long-lived core, while X is a variable representing potential electrical outputs of 5, 10 or 20 MWe. The objective of this conceptual design is to implement the simplifications embodied in the LFR-AS-200 in a family of very small reactors with

a similar level of compactness and simplification. Table 10 provides selected parameters of the LFR-TL-X, and Fig. 10 provides sketches of both LFR-AS-200 and LFR-TL-X.

MicroURANUS

Nuclear scientists and engineers at Seoul National University and elsewhere in the Republic of Korea have a long history of conceptualizing and developing HLM-cooled fast SMRs. Most recently, they have pursued a new land-transportable micro reactor concept,

the MicroURANUS system which is a 20 MWe LBE-cooled system targeted for hydrogen production and maritime power. The term URANUS is an acronym derived from the following characteristics: Ubiquitous, Robust, Accident-forgiving, Non-proliferating and Ultra-lasting Sustainer.

The MicroURANUS development, led by researchers at the Ulsan National Institute of Science and Technology (UNIST), keys on the following features: The system would be long-lived and would be designed as a non-refueling modular LFR. After its full operational life, the MicroURANUS reactor would be removed with its fuel contained in the reactor vessel and transported by shipping cask to an international recycling center for secure processing. Recovered heavy actinide constituents from spent fuel processing as well as trace long-lived nuclides would be refabricated into fuels for future MicroURANUS units. Table 11 provides selected parameters of the MicroURANUS reactor, and Fig. 11 provides a sketch.

Special potential applications

Having summarized ongoing developments related to HLM-cooled fast SMRs, it is worthwhile to note some especially suitable applications beyond simple production of electricity and other energy-related products to meet local or regional requirements. Two such applications are (1) to meet the needs of isolated communities (e.g., islands or communities isolated by severe climate conditions such as the Arctic), and (2) commercial maritime applications.

To meet the energy product needs of remote or isolated locations (including those in developing parts of the world for which power distribution infrastructures are poorly established), important considerations include transportability, compactness, passive safety, very long core life and autonomous operations. HLM-cooled fast SMRs envisioned to date excel in meeting these goals. Examples include SSTAR, SEALER and others – deliberately designed to achieve such objectives by capitalizing on the intrinsic characteristics of HLM coolants. Note that the Hydromine LFR-AS-200, for example, achieves a compactness milestone of >1 MWe per m³ of primary system volume.

A second special application of note is that of commercial maritime propulsion, an application receiving increasing attention as it is recognized that current commercial shipping contributes significantly to the CO₂ release to the atmosphere. (Haas, 2014) Two HLM-cooled fast SMR concepts are actively targeting this area of application: MicroURANUS and the Hydromine LFR-TL-X. Table 12 summarizes the benefits from the maritime ship propulsion application.

Fig. 11 Sketch of MicroURANUS (IAEA, 2020).

Table 12 Maritime ship propulsion benefits.

<i>Desired feature</i>	<i>HLM-cooled fast SMR characteristics</i>	<i>Implications for ship propulsion</i>
Passive safety/ simplified design	- HLM-cooled small fast reactors feature a high level of intrinsic passive safety - relative chemical inertness of lead - high boiling temperature - ability to operate at atmospheric conditions - favorable thermo-hydraulic properties that support natural circulation heat removal	Simplified design and operation result in high reliability, low maintenance operations over very long time frames
Safety in the event of catastrophic occurrence	In the event of catastrophic occurrence, the core becomes encapsulated in the frozen lead coolant and prevents release of significant radioactivity	Eliminates the potential for environmental dispersion of contaminants in the event of otherwise catastrophic conditions
Compactness	HLM-cooled SMR designs are very compact	Reduced volume frees up cargo capacity. Elimination of the need for diesel fuel storage also increases cargo capacity
Very Long refueling interval/sealed system	These systems can operate for 15–30 years without refueling	Eliminates service outages/routing restrictions for refueling; eliminates safety issues with fuel transfer operations

Summary and conclusions

This chapter has reviewed HLM-cooled Fast SMRs. While HLM coolants have been considered since the earliest days of nuclear reactor technology, in recent years development activity has rapidly accelerated. The Russian systems SVBR-100 and BREST-OD-300 benefited from design and operational experience during the Cold-War application of HLM-cooled reactors to submarine propulsion, while other applications have reflected broad global HLM-cooled fast SMR interest (e.g., ALFRED and Sealer in the EU; SSTAR in the US; Hydromine LFRs in the US and Europe; CLEAR-M in China; and MicroURANUS in the Republic of Korea).

Different options for heavy liquid metal coolants having been explored, nearly all current activity is focused on either lead or LBE coolants. The engineering challenges associated with their significant differences in melting temperatures and production rates of polonium-210 are important in the choice between these coolants, and to date both options are represented in different ongoing reactor development activities.

The fundamental characteristics of these coolants are very favorable for fast reactor operations by virtue of their impacts on reactor neutronics as well as thermal hydraulics. The lack of rapid and energetic reactions with water and air eliminate the need for an intermediate cooling circuit to isolate activated primary coolant from steam, water or air, and this promotes system simplification, economic performance and inherent safety. Likewise, the very high boiling temperatures and low vapor pressures of both of these coolants enable operation near atmospheric pressure and virtually eliminate the possibility for coolant boiling or coolant vapor voids in the primary system.

Several current and recent HLM-cooled fast SMR concepts were summarized, including those that are designed as SMRs, and those that are demonstrator units intended to support scale up for future full-size units. In each case, the fundamental characteristics of the coolant have been taken into account to provide designs that are highly compact, passively safe, efficient in both electricity generation and fuel utilization. Some special applications, including units intended for remote and isolated locations and units appropriate for maritime propulsion, were also discussed.

Historical background

In the early 1950s, the United States and USSR military forces developed micro-reactors for use as power supply on military bases disconnected from national grids. The typical electrical power requirement of such bases is a few MW. Four of the water-cooled US reactors listed in [Table 1](#) (PM-2A, PM-3A, SM-1A and MH-1A) were constructed, shipped to a remote destination and operated for a number of years before being returned to mainland US for decommissioning ([Suid, 1990](#); [DOE, 2001](#)). The USSR reactors were intended to be truck- or tank mounted, but were operationally tested on the site of the institute where they were developed ([Sinev et al., 1964](#); [Paliukhovich, 2002](#); [Baranaev et al., 1997](#)).

In particular, the PM-2A reactor deployed 220 km north-east of Thule base on Greenland deserves special attention ([Clark, 1965](#)). The reactor was transported to site on sleigh over the ice-cap, for installation in a 12 m wide trench buried under a surface of snow. A staff of 18 operated the plant. The cost of designing, building and installing the plant on Camp Century is stated by Clark as (1961) USD 5.7 million, equivalent to USD 49 million in 2019. Operating costs are quoted as 6.5 cents/kWh in 1961 currency, or 0.56 USD/kWh in today's value. Initial problems with the turbine generator lead to three extended shutdowns in 1961, whereas in 1962, the reactor operated with 74% availability, producing 5.4 GWh of electrical energy. In 1964, the reactor was disassembled, removed from Camp Century and returned to the United States.

Concepts under development

This article is addressing micro-reactor concepts and designs rated at maximum 10 MWe. It is complementary to [Cochran and Lovering \(2021\)](#), which is expanding the considered reactor power to the > 10 MWe and < 50 MWe range, thus addressing also reactors in the SMR category ([Table 2](#)).

In what follows, these concepts are described in terms of their particular design solutions, to the extent that this information is available in the open literature.

Toshiba's 4S-design

4S is short for "Super-Safe, Small and Simple." It is a sodium cooled reactor design with metallic fuel that was developed by Toshiba in order to reconcile demands for safety and economics ([Ueda et al., 2005](#)). It is intended for deployment in Arctic and other remote areas.

The final 10 MWe (30 MWth) version of 4S features a core with an active fuel height of 2.5 m and 18 hexagonal fuel assemblies with 169 fuel rods each ([IAEA, 2007](#)). The fuel rod has an outer diameter of 10.0 mm, and a cladding thickness of 0.50 mm. The U–Zr metallic alloy fuel has a ^{235}U enrichment of 17/19%, leading to a reactivity loss of 5500 pcm during the intended 30-year lifetime at an average linear power of 3.9 kW/m, during which the fuel reaches an average burn-up of 34 GWd/t. All reactivity coefficients of the core are negative, but due to fission product accumulation, the neutron spectrum softens, and the coolant temperature feedback becomes less negative and reaches a net-zero value at end-of-life. The reactivity loss of the core is compensated by a combination of a fixed absorber rod that is lifted out of the core at middle-of-life, and a cylindrical silicon-carbide reflector being lifted from beneath the core toward the top.

The primary sodium inlet/outlet temperatures are 355 °C and 510 °C respectively. Cooling during normal operation is achieved by forced convection using an EM-pump and an intermediate heat-exchanger located in a separate vessel. The height of the reactor vessel is 14 m, in order to permit passive removal of decay heat.

Toshiba proposed to demonstrate the 4S concept in Galena, an Alaskan community. Whereas the city council of Galena was positive to the project ([Alaska Journal of Commerce, 2008](#)), it did not proceed to licensing.

Table 1 Micro-reactors operated or tested by US and USSR military forces.

Name	Coolant	Power	Operator	Location	BoL	EoL
PM-1	H ₂ O	1 MWe	US army	Sundance, Wyoming	1962	1968
PM-2A	H ₂ O	1.6 MWe	US army	Camp Century, Greenland	1960	1963

UNITHERM	NIKIET	H ₂ O	6 MWe	UO ₂ -Zr	Desalination, process steam

OKBM's ABV-6M design

The 6–9 MWe version of OKBM's ABV design is a factory produced PWR for use on floating nuclear plants, that would supply heat and desalination services, in addition to power (IAEA, 2012). An ²³⁵U enrichment of 19.7% gives the core an operational life of 10–12 years.

The total reactor module has a mass of 600 tons, a height of 13 m and a diameter of 8.5 m. The reactor is designed to be able to drive a floating nuclear power plant with a maximum length of 140 m, a beam of 21 m, a draft of 2.8 m and a displacement of 8700 t. Depending on the needs of the region to where it is shipped, the floating nuclear power plant can generate electric power, provide heat and power cogeneration, heat generation for sea water desalination, or can be used for other industrial applications.

The core lifetime is 10 years with 16,000 h of continuous operation, without reloading or shuffling of fuel.

The inlet/outlet temperature of the primary coolant is 247/330 °C, operating under a pressure of 15.7 MPa. Passive safety is implemented by natural convection of the primary coolant for removal of full power.

Gidropress' Angstrom design

Gidropress ("Hydropress") designs the Angstrom plant to achieve passive safety features in conjunction with a very short factory construction time of 12 months (Stepanov et al., 1998).

The 30 MWth (6 MWe) plant operates on lead-bismuth eutectic as primary coolant and may produce up to 14 MW of heat. Its core consists of about 2500 UO₂ fuel rods with an active fuel height of 0.7 m, an outer fuel rod diameter of 12.0 mm and a cladding thickness of 0.4 mm. The enrichment of the fuel is 26% and the peak fuel burn-up 8.6% (86 GWd/ton). At an average linear power of 17 kW/m, the effective full power life of the core is 8 years.

The primary coolant inlet/outlet temperatures are 290 °C and 465 °C, respectively, and the steam generator operates at a pressure of 3.5 MPa. The transportable steam supply system module of the plant, enclosing the reactor unit, steam generators, pump tanks, condensers and radiators, has a dimension of 5.1 × 3.2 × 24.4 m.

OKLO's Aurora design

Aurora is a 1.5 MWe (4 MWth) potassium heat-pipe reactor designed by OKLO. It utilizes uranium-zirconium metal alloy fuel and the reactor is to be located underground. A license application has been submitted to US NRC (OKLO, 2020). The intended market is "communities."

Heat exchange from the primary system is provided by super-critical CO₂.

Aurora has negative reactivity feedbacks due to thermal expansion of the fuel and structural materials, as well as doppler broadening.

Three control drums are used to control reactivity. Three shut-down rods are suspended above the core by electromagnets such that the rods insert via gravity drop when the electromagnets are de-energized.

Decay heat is passively transported from the fuel through the zirconium based reflector to thermal heat sinks within the reactor module.

INEST's CLEAR-M design

CLEAR-M10d is a 10 MWe lead-cooled reactor design by INEST (Wu et al., 2019). It is fueled with 18.0–19.75% enriched UO₂, having a core-life of 10–20 years, corresponding to a burn-up of 62 GWd/t. The core consists of 3500 fuel rods with an outer diameter of 16 mm, a cladding thickness of 1 mm, and a rod pitch to diameter ratio of 1.2. The active fuel height is 1.2 m.

The primary coolant inlet/outlet temperature is 375/495 °C. The average velocity of the coolant is 0.46 m/s, yielding a maximum cladding temperature of 541 °C.

A single spiral tube steam generator is used for heat transfer, having an outer diameter of 1.75 m and a bundle active height of 1.46 m.

Decay heat removal is achieved by natural convection in a primary vessel having a height of 8.5 m and a diameter of 2.5 m.

Westinghouse's eVinci design

The eVinci reactor is designed by Westinghouse to achieve passive heat extraction using liquid sodium heat pipes (Arafat and Van Wyk, 2019). The electrical power of the reactor is between 0.2 and 5 MW. It is designed to be manufactured and fueled in a factory for transport to site, where installation would be made within 30 days. The core is designed as a steel monolith with channels for heat pipes and fuel pellets, requiring refueling after 10 years. The secondary coolant temperature reaches 600 °C, enabling process heat applications. The uranium fuel may be either an oxide, silicide, or metal alloy.

The intended markets of e-Vinci are Arctic regions and military bases (Fig. 1).

USNC's MMR design

The US based Ultra-safe Nuclear Corporation is developing a 5 MWe helium cooled reactor with coated particle TRISO fuel in a prismatic block configuration. A core lifetime of 20 years without refueling is foreseen. The intermediate heat transfer medium is a molten salt. In 2019, USNC's Canadian partner Global First Power filed an application for license to build a demonstration unit on the Chalk River site of Canadian Nuclear Laboratories in Canada (Global First Power, 2019). The intended markets for the MMR are remote communities and mining operations in Arctic regions (Fig. 2).

LeadCold's SEALER design

LeadCold has designed a lead-cooled reactor for power production in Arctic communities and mining operations (Wallenius et al., 2018). The core consists of 19 fuel assemblies with 19.75% enriched UO_2 fuel, surrounded by 12 control rod assemblies and six shut-down rod assemblies. Each fuel assembly hosts 91 fuel rods with an outer diameter of 14.4 mm, a clad thickness of 0.5 mm and a pellet diameter of 13.3 mm. The fuel column height is 1.1 m, and the total rod length 1.59 m. The 15–15Ti cladding is protected from corrosion by a surface alloy consisting of Fe–10Cr–6Al–RE, where RE stands for an optimized composition of Ti, Zr, Nb and Y.

When deployed in an Arctic community, it would operate at 8 MW of thermal power (maximum 3 MWe), corresponding to an average linear power of 4.2 kW/m. The average burn-up is limited by reactivity losses and available control-rod compensation worth of 4500 pcm to 33 GWd/ton, which in this operational mode is achieved after 27 full power years. In this case, the coolant inlet/outlet temperature is limited to 390/432 °C, permitting the use of conventional SS316 steel as structural material in the reactor. The end-of-life peak damage dose to the fuel cladding is 66 dpa.

If deployed at a mining site, the reactor would operate at 25 MW of thermal power (maximum 10 MWe), corresponding to a linear power of 13 kW/m, and a coolant outlet temperature of 520 °C. The core-life in this case is nine full power years, which corresponds to the typical duration of a remote mining business (IAEA, 2007). In this case, all pressure boundary materials exposed to lead have to be protected by an alumina forming weld overlay, while structures under low stress may be manufactured by bulk Fe–10Cr–4Al–RE (Fig. 3).

U-battery

U-Battery is a consortium including URENCO, Wood, Laing O'Rourke and Kinetrics. Its 9 MWe (21 MWth) helium cooled reactor was designed by Manchester University and the University of Delft to operate on coated particle TRISO fuel embedded in prismatic blocs (Ding et al., 2011). The core consists of 120 blocks stacked in four horizontal levels, including seven internal reflector blocks in each level. The inventory of 19.75% enriched UO_2 fuel is 1.8 tons and the packing fraction of microspheres in the fuel compacts is 30%. The core is refueled each 5 years, during which the fuel reaches 90 GWd/tburn-up.

The coolant inlet/outlet temperature is 420/750 °C, and power is produced by a nitrogen turbine.

The intended market for U-Battery is process heat for industrial applications where the first demo-unit would be powering the industrial site of URENCO in Capenhurst (Fig. 4).

NIKIET's UNITHERM design

The water-cooled UNITHERM design of NIKIET is intended for production of a mixture of electricity, district heating, seawater desalination, and process steam production, or to meet other specific demands (IAEA, 2007). The reactor would be produced in a factory shop.

The 30 MWth (2.5–6.0 MWe) power unit uses a CerMet (Ceramic-Metallic composite) UO_2 –Zr fuel with 19.75% enrichment of ^{235}U , in a zircalloy cladding tube. The cladding tube features four helical ribs, used as rod spacers. The inner/outer cladding diameter is 4.8/5.8 mm. The fuel rods are arranged in a hexagonal pattern having a pitch of 7.05 mm, in cylindrical fuel assemblies with an inner/outer shroud diameter of 58.4/60.0 mm.

An average/peak burn-up of the fuel equal to 110/180 GWd/t is foreseen. The core features 265 fuel assemblies, a diameter of 1.13 m and an active fuel height of 1.1 m. A particular feature of this design is a very low fuel temperature, estimated at 365 °C. The life-time of the fuel is 16.5 full power years. Reactivity loss during operation of the core is not provided by NIKIET, yet is supposed to be compensated by 9 control assemblies with 53 or 54 absorber rods each.

The primary coolant inlet/outlet temperatures are 250/330 °C, respectively, operating under a pressure of 16.5 MPa. The dimension of the primary vessel is 3.22×5.05 m for the case of producing 20 MWth of steam and 2.5 MW of electricity, and 3.33×6.15 m for a system producing 6 MW of electricity.

R&D required for commercial applications

Water-cooled reactors

The water-cooled ABV-6M reactor applies conventional oxide fuel, hence the design is of mature character, and requires little R&D to be qualified, with the possible exception of the particular solution for passive decay heat removal, which is natural convection of the primary coolant.

Fig. 4 U-Battery plant configuration. Reprinted with permission of U-Battery limited.

NIKIET's UNITHERM's concept relies on the use of $\text{UO}_2\text{-Zr}$ composite CERMET fuel, which has not been used in commercial power plants. The fuel manufacturing route has to be qualified by means of irradiation in test reactors of fuel produced by an industrial fuel supplier with the actual process foreseen by NIKIET.

Helium-cooled reactors

Whereas high temperature micro-reactor designs of U-Battery and USNC rely on proven technology in terms of the primary cooling circuit and the coated-particle fuel, these concepts have to qualify their respective industrial (i.e. non-prototype) fuel manufacturing route by irradiation in materials test reactors or a demonstration unit prior to commercial operation.

A remaining phenomenon of possible concern for radiological exposure to maintenance staff is the observed migration of silver fission products through intact TRISO encapsulation of fuel kernels (Geng, 2014; van Rooyen et al., 2014).

Sodium-cooled reactors

Licensing of Toshiba's 4S design will require the demonstration of its reactivity control system, which consists of an annular absorber ring surrounding the core. In particular, passive response to control element ejection must be evaluated. As for other concepts, the U-Zr fuel manufacturing route needs to be qualified by irradiation in a materials test or a demonstration reactor.

The eVinci concept of Westinghouse is considerably more innovative, e.g. in terms of its horizontal configuration. In particular the functionality and materials performance of sodium heat pipes during extended operation mandates investigation. It is to be noted that the lab-scale tests of the technology conducted to date were made for potassium heat pipes, an element having a substantially lower evaporation temperature. Use of a silicide or metal alloy fuel will require qualification of the respective manufacturing route to be used in an actual industrial fuel manufacturing facility.

Lead- and lead-bismuth-cooled reactors

The long-term application of LeadCold's SEALER-unit requires the qualification of alumina forming steels for corrosion protection of fuel cladding tubes, steam generator tubes and hex-cans. Lab observations indicating excellent corrosion tolerance at $T = 550\text{--}850\text{ }^\circ\text{C}$ need to be confirmed under prototypical flowing lead and varying oxygen conditions (Ejenstam et al., 2013; Dörmstedt et al., 2020).

In the case of the ANGSTREM design, a similar qualification program is required for the Fe-12Cr-2Si steel developed in Russia for heavy liquid metal cooled reactors. A particular difficulty with the latter appears to be low temperature irradiation embrittlement.

The structural material to be used for corrosion mitigation in CLEAR-M10d appears not to be defined. Once the approach is defined, it has to be verified through a program including exposure under flowing lead as well as under irradiation.

All lead-cooled micro-reactors here listed intend to use conventional UO_2 fuel, for which no further qualification appears to be necessary.

Glossary

CR Conversion ratio—Fissile material production rate relative to its loss rate in a system.

DC Doppler coefficient of reactivity—Change in core reactivity per unit change in fuel temperature due to Doppler broadening of resonances in fuel nuclides.

HFP Hot full power—Operating condition at which all reactor component temperatures are at their nominal values.

HZP Hot zero power—Operating condition at which reactor coolant and fuel temperatures are lower than their nominal values. Only the coolant temperature at the core inlet is nominal. However, since the core does not generate power, the coolant is not heated up as it flows along the fuel rods. Furthermore, there is also no temperature difference between the fuel pellet surface and its center.

MA Minor actinides; isotopes of neptunium, americium, curium and heavier elements.

MTC Moderator temperature coefficient—Change in core reactivity per unit change in moderator temperature. The reactivity effect is related to the balance between neutron absorption and neutron moderation effects, both of which change to a different extent due to thermal expansion of the moderator (light water coolant in case of LWR).

MWd/kg A measure of fuel burnup: the amount of energy in MW-days produced per kg of initial uranium (or any other Heavy Metal—HM) content in the fuel.

Neutron spectrum Relative energy distribution of neutron flux. It is measured in number of neutrons/cm²/s/eV. The spectrum is said to be hardening, if the relative distribution of neutrons shifts towards higher energies, while opposite is the in case for spectrum softening.

Radiotoxicity Effective radiation dose to human body in Sieverts (Sv) per given quantity of radioactive nuclide either ingested or inhaled. It accounts for the specific activity of the nuclide (i.e., its half-life), type of radiation it emits and relative damaging effects to biological tissues affected by the radiation.

Reactivity Fraction of neutrons in a reactor in excess of what is required for perfect balance between the neutron production and loss rates. Reactivity is equal to zero when such balance is achieved. In that case, the system is said to be critical and its neutron population remains stable.

Reactivity excess Positive reactivity of fresh nuclear fuel which needs to be compensated by various reactivity control means such as control rods, soluble boron and burnable poisons in order to keep the system critical during normal operation at full power.

Reactivity worth Change in reactivity as a result of introduction of unit of absorbing material into the system—e.g., insertion of a control rod or change in soluble boron concentration.

SDM Shutdown margin—Difference between core reactivity at Hot Full Power and Hot Zero Power (see above the definitions of HFP and HZP). Since both DC and MTC are typically negative, cooling down of the core will result in an increase in reactivity which must be compensated by insertion of control rods or other means to assure sub-criticality in case of an emergency shutdown. Several conservative assumptions are typically applied when calculating SDM, such as assuming that the most reactive control rod is stuck out (failed to insert) as well as various engineering and modeling uncertainties.

TRU Transuranic nuclides—Plutonium and minor actinides.

Commercial LWR used fuel characteristics

The vast majority of currently operating commercial nuclear power reactors are of the Light Water-cooled Reactor (LWR) type. Most LWRs use an open fuel cycle. This mode of operation implies that the fuel used in the reactors is manufactured from freshly mined uranium, which is subsequently enriched and fabricated into fuel rod assemblies. After irradiation, used fuel is cooled for a number of years in water pools on reactor sites and, when its activity is reduced, is typically moved to interim air-cooled concrete storage casks awaiting ultimate disposal in a geological repository when it becomes available (Glatz, 2021). Several countries (e.g., Finland, Sweden and France) have been successful in identifying suitable geological formations for the final disposal of radioactive waste and are now at different stages of design, licensing and construction of these facilities (Kadak, 2021). In other countries, used nuclear fuel repository siting and approval has faced significant public opposition with no clear pathway for resolution (Metlay, 2021). The use of deep boreholes is a potentially attractive alternative to a centralized repository. This emerging technology benefits from a smaller footprint and a wider availability of suitable sites. Their modular nature may also result in a lower marginal cost of capacity expansion.

The need for a geological repository arises from the fact that used nuclear fuel contains radioactive nuclides which need to be isolated from the environment for long periods of time to prevent harm to humans and the biosphere in general. The half-life for radioactive decay of some of these nuclides, however, is substantially longer than the time over which the integrity of engineered isolation barriers can be assured. Therefore, the safety case for an ultimate repository must rely on local geological characteristics to ensure that radioactive nuclides do not enter the biosphere. Studies of natural analogues, most notably a natural nuclear reactor at Oklo, Gabon provide a robust scientific basis for the licensing of radioactive waste repositories (Gauthier-Lafaye, 2002).

Before presenting the reasons for recycling used nuclear fuel, it is worthwhile examining the constituents of the fuel following irradiation and discharge from a typical LWR (Glatz, 2021). The cumulative thermal energy produced by each kilogram of a typical LWR used fuel is on the order of 50 Mega-Watt-days (MW-days or 1.2 million kWh). This amount of energy corresponds to about 5% of the initial uranium atoms having been fissioned and converted into fission products (FP). It means that the FPs constitute about 5% of the used fuel mass, while the originally loaded uranium still accounts for the majority of the rest of the fuel, or about 94% (Fig. 1). The remaining uranium is only mildly radioactive and still contains about the same amount of fissile ²³⁵U as natural uranium. Recycled uranium can be re-enriched and re-used in LWRs, although a somewhat higher enrichment would be required because of the presence of ²³⁶U, which is a moderately strong neutron absorber.

The fission products include many isotopes, the majority of which are highly radioactive. Heavy nuclides such as uranium require many neutrons to provide stability of their nuclei. When split in fission into two (or more) fission products, the resulting lighter nuclei do not require as many neutrons for stability. Such excess of neutrons is energetically unfavorable and leads to spontaneous radioactive decay. High radioactivity implies short half-life. As a result, the vast majority of FPs decay to negligible activity levels in a few hundred years. Most of the FPs also have a relatively low mobility in the environment, so that they will stay within or close to the waste package even after it is degraded.

The high radioactivity of FPs also means that used fuel needs to be cooled for long periods of time after discharge from a reactor core to avoid reaching temperatures that would compromise its integrity or the integrity of the waste package. Therefore, the management of decay heat produced by spent used fuel remains an important consideration for the design of all facilities involved in the spent used fuel handling. Most of the decay heat in the time period relevant to interim storage and disposal of used fuel is produced by only two FP isotopes: ¹³⁷Cs and ⁹⁰Sr, both with half-lives of approximately 30 years. Both isotopes are produced in fission with a high probability and are therefore present in used fuel in high concentrations. From about 10 years following fuel discharge, Cs, Sr and their short-lived decay chain daughters dominate the heat generation, accounting for over 90% of the heat generated by FP decay for several decades.

Fig. 1 Composition of a typical LWR used nuclear fuel.

Modern LWRs produce, through successive neutron captures starting in ^{238}U and radioactive decay (Shusterman, 2021), about 250 kg of Pu per Giga-Watt-years (GW-year) of electricity they produce. Plutonium comprises approximately 1% of used LWR fuel mass. A significant fraction of this is made up of the fissile isotopes ^{239}Pu and ^{241}Pu , with properties similar to ^{235}U . Plutonium isotopes are more radioactive than uranium and, if separated from the rest of the used fuel constituents, produce non-negligible amount of decay heat and require shielding for handling. The radioactive decay of some of plutonium isotopes, however, is not sufficiently fast to avoid the requirement for geological isolation.

The remainder of the used fuel mass is composed of actinides other than uranium and plutonium. Their cumulative fraction is typically small—on the order of 0.1%. Therefore, these are collectively known as Minor Actinides (MA), while, together with plutonium, these are referred to as Trans-Uranium elements (or TRU) because they are located beyond uranium in the Periodic Table. MAs are produced as a result of a series of neutron captures and subsequent decays, starting from uranium and plutonium isotopes. Despite their small quantity, some MA have long half-lives and high mobility in the environment. Therefore, they, like plutonium, require geological isolation. Moreover, many MA isotopes generate not just decay heat but also emit high-energy photons and/or neutrons, further complicating handling, transportation and storage of used fuel.

Motivations for Used Fuel Recycling

Several reasons have been identified to justify recycling some of the constituents of irradiated nuclear fuel from LWRs. The recycling of some subsets of these has been deemed sufficiently valuable to spur industrial scale technology development and commercial deployment. The recycling of other constituents has remained a mostly academic exercise with small-scale lab based experimental programs. The practice of recycling and re-use of any of the used fuel constituents is often referred to as a closed fuel cycle.

Historically, the primary reason for recycling used nuclear fuel from commercial power reactors has been the desire to recover the energy value remaining in the fuel after discharge. As briefly described in Chapter 00308, uranium from used fuel can be either re-enriched or mixed with plutonium, also recovered from used fuel, then refabricated into new fuel which would continue generating energy. The recycling of uranium and plutonium from used fuel can also be viewed as an assurance of energy security, in case the supply of energy resources (either nuclear or otherwise) is interrupted due to hard-to-predict events such as natural disasters or military conflicts.

Another reason for recycling is to enable an alternative (to the open fuel cycle) approach to radioactive waste management, perhaps increasing the capacity or simplifying the design of the geological repository. Separating out environmentally mobile nuclides results in less reliance needing to be placed on engineered barriers. Separating out the long-lived nuclides means that any barriers, either engineered or geological, need to perform their role for a shorter period. The long-lived nuclides can be re-introduced into reactor cores, where they can be fissioned directly or transmuted into other nuclides with a shorter half-life or with better fissile properties which can also eventually fission and, thus, be converted into short-lived fission products.

An extensive study conducted by the US DOE concluded that a used fuel repository capacity can be increased by up to a factor of 43 if 99.9% of Cs and Sr, Am and Pu are separated and not sent to geological disposal, as illustrated in Fig. 2 (Wigeland et al., 2006). Separated Cs and Sr would be stored in a supervised interim storage, while the Am and Pu would be recycled and transmuted within a closed fuel cycle.

In addition to realizing the energy potential of recycled uranium and plutonium or transmuting long-lived MA nuclides, separation of short-lived FPs from uranium, Pu and MA also provides an opportunity to recondition the components that are not recycled and destined for the repository into more environmentally-robust waste forms such as glasses or ceramics.

Fig. 2 Geological repository compaction factors for different efficiencies of MA and FP separation. From Wigeland RA, Bauer TH, Fanning TH, and Morris EE (2006) Separations and transmutation criteria to improve utilization of a geologic repository. *Nuclear Technology*, 154(1): 95–106.

Finally, the recycling of fissile actinides may also prevent diversion of these nuclides to weapons proliferation. Eliminating the potential for the diversion of fissile material from the used fuel repository, however, does not eliminate the risk of proliferation altogether; other opportunities of diversion from various stages of the closed fuel cycle will arise. Therefore, weighing the risks of proliferation between the open and closed fuel cycles is a subject of vibrant research and ongoing public debate.

The various options for used fuel recycling can be distinguished by which components of the fuel are chosen to be recycled: Pu, MA, and sometimes Long-lived Fission Products (LLFP) e.g., ^{129}I and ^{99}Tc , or any combination of the above. In addition, recycling these components could be done only once, multiple times, or indefinitely. The latter option implies that these nuclides are kept within the fuel cycle and never leak into the environment apart from losses arising as a result of imperfect reprocessing methods. Finally, different materials have been considered as host matrices for recycling, such as UO_2 , ThO_2 or neutronically inert matrix fuels (IMF), also known as Fertile-Free Fuels (FFF). It is legitimate to investigate at least the theoretical possibility of all these options. The environmental benefits of recycling increase with more components being recycled and with the number of recycling passes, but so do the technological complexity and costs of such fuel cycles. The remainder of this chapter will discuss some of the benefits and practical limitations of these options, focusing mostly on the implications for reactor operation and design.

Single-Pass Recycling of Pu and MA in LWRs

Recycling Pu in commercial LWRs has been carried out successfully for several decades in many countries. The motivations for this practice have been mainly the realization of additional energy value stored in used nuclear fuel and conditioning of FPs and MAs in carefully engineered glass (through a process called vitrification) for long-term storage or disposal.

In this scenario, used fuel is reprocessed to separate plutonium and uranium from the rest of the used fuel constituents using the PUREX process or its derivatives (Genetz, 2021). It involves mechanical shredding of the fuel with subsequent dissolution in nitric acid, from which U and Pu are selectively removed using the organic molecule tributyl phosphate (or TBP). This process has been demonstrated on an industrial scale with a total global capacity of several thousand tons of reprocessed fuel per year. The largest existing LWR reprocessing operation is in La Hague, France. Oxide fuel reprocessing in the United Kingdom at Sellafield THORP plant was terminated in 2018 due to a lack of commercial demand, while a large-scale reprocessing plant at Rokkasho, Japan, has been recently completed after a lengthy construction and licensing period but has not yet entered its full commercial operation at the time of writing. In the US, following a brief politically motivated ban on fuel reprocessing in the late 70s due to concerns over nuclear weapons proliferation, commercial fuel reprocessing has never been restarted, although scientific research is ongoing with state-of-the-art capabilities in many universities and national laboratories.

The preferred fuel of choice for recycling Pu from used nuclear fuel in LWRs is Mixed Oxide (MOX). In this fuel form, PuO_2 is mixed with UO_2 which can either be fresh natural uranium, depleted uranium from enrichment process tailings or recycled uranium from used fuel.

The evolution of Pu isotopes with burnup in a typical LWR is presented in Fig. 6 in Shwageraus (2021). At a typical burnup of about 50 MWd/kg, used LWR fuel would contain a mixture of Pu isotopes with only about 65% of them being fissile in a thermal spectrum. All Pu isotopes are strong absorbers of thermal neutrons. This is the main cause of MOX fuel's implications for LWR core design and operation. Each Pu isotope has its own peculiar features that are relevant to the practicality of using MOX in LWRs.

^{238}Pu appears in relatively small quantities of around 2–3%. It is not fissile in a thermal spectrum but can be converted to fissile ^{239}Pu through neutron capture. It has a relatively short α -decay half-life of about 87 years which, in addition to a high spontaneous fission probability, can be viewed as providing an important deterrent against nuclear proliferation (see also [Shwageraus, 2021](#) for additional discussion). However, high levels of decay heat also complicate MOX fuel manufacturing and handling, which can be overcome in principle with technological solutions such as remote operations and active cooling, but these will inevitably add costs to the fuel cycle.

^{239}Pu is the main fissile isotope with the highest concentration of around 50% in typical used LWR fuel. It has a much higher thermal fission cross-section than ^{235}U , which makes it a dominant consumer of thermal neutrons in the fuel, leading to a substantially harder neutron spectrum than in uranium fuel. It also has much higher resonance integral than ^{235}U with a strong low-energy resonance at about 0.3 eV, which makes MOX fuel more sensitive to spectral shifts due to changes in temperatures and densities of core materials. The probability of neutron capture without fission in ^{239}Pu is also substantially higher than in ^{235}U , leading to significant generation of ^{240}Pu .

^{240}Pu is not fissile. It comprises about a quarter of LWR-grade Pu. Its importance lies in the fact that it has a giant low-energy resonance (about 100,000 barn at its peak). As for ^{239}Pu , this makes MOX fuel particularly sensitive to spectral changes. Because of its large absorption cross section, it is an excellent source of fissile ^{241}Pu .

^{241}Pu has similar fissile properties to those of ^{239}Pu . At discharge, it constitutes a notable fraction (about 15%) of total Pu. However, it has relatively short half-life of 14 years, decaying to ^{241}Am . This means that the Pu fissile content is sensitive to both cooling time before reprocessing and the subsequent storage time of already separated Pu. The latter matters also because the presence of ^{241}Am further complicates MOX fuel manufacturing and handling due to decay heat and γ -radiation dose resulting from ^{241}Am decay. Additionally, ^{241}Am is a strong neutron absorber contributing further to Pu fuel reactivity loss in addition to that arising from the loss of fissile ^{241}Pu .

^{242}Pu is very similar to ^{238}Pu in terms of its relevant neutron reactions. It is, however, much longer-lived (nearly 400,000 years). Unlike ^{238}Pu , it does not directly produce a fissile isotope and, therefore, it is essentially just a parasitic neutron absorber. Furthermore, the decay of ^{241}Pu and neutron captures in ^{242}Pu are the two main routes to production of minor actinides such as americium and curium isotopes, recycling of which in LWRs adds an additional layer of complexity, as will be discussed later.

Implications of using Pu MOX for LWR operation and core design

As mentioned earlier, the strong thermal absorption of Pu isotopes leads to a hardening of the neutron spectrum when MOX fuel is introduced to an LWR core. As a result of that, the relative competitiveness of other core materials for neutron absorption diminishes. For example, the reactivity worth of soluble boron and control rods is significantly reduced. Therefore, LWRs loaded with MOX fuel will have a reduced control rod shutdown margin.

The operational flexibility of existing reactors is often limited, and it is not always possible to increase the soluble boron concentration to make up for this change because of the constraints imposed by needing to avoid a positive Moderator Temperature Coefficient (MTC) and coolant water chemistry. The loss of soluble boron reactivity worth is partially compensated by the fact that MOX fuel has flatter reactivity as a function of burnup than UO_2 fuel. Therefore, there may be less initial excess reactivity to compensate for.

These considerations currently restrict the fraction of MOX fuel assemblies in existing LWRs to about one third, while the remainder are conventional slightly enriched UO_2 fuel assemblies. Modern, Gen-III+ LWR designs have provisions such as a larger number of control rods to accommodate a full MOX fuel core ([Arslan et al., 2013](#)).

MOX fuel assembly designs are slightly different from conventional UO_2 LWR fuel assemblies. Non-uniformity in the amount of water around fuel pins across a fuel assembly (next to inter-assembly gaps or control rod guide tubes) leads to slight variations in neutron spectrum. This has a negligible effect on UO_2 fuel. Pu bearing fuel, however, is very sensitive to spectrum variation due to low-energy resonances and high thermal neutron absorption cross section. This can result in a greater variation of power across the fuel assembly. Therefore, fuel pins in MOX assemblies typically have varied concentration of Pu in order to compensate for this. Three different Pu loadings are common for PWR MOX, while in BWRs, up to six different Pu loadings are used because of the generally higher heterogeneity of BWR fuel assemblies.

In partially MOX fuel loaded LWR cores, MOX fuel assemblies tend to operate at higher power towards the end of life because of the flatter reactivity decline with burnup than that of UO_2 assemblies. This is undesirable because high power in high-burnup assemblies may lead to an excessive release of fission gas, limiting the achievable fuel burnup.

Both the Doppler effect and MTC in MOX fuel assemblies are more negative than in UO_2 fuel, again, due to the low-energy resonances in fertile Pu isotopes. This effect leads to a further deterioration of shutdown margin because the reactivity increase due to fuel and moderator cooling from Hot Full Power (HFP) to Hot Zero Power (HZP) conditions will be larger. Therefore, even larger number of control rods will be required, further restricting the fraction of MOX assemblies in conventional LWR cores.

An additional complication related to resonance structure of Pu isotopes is a potential reactivity insertion due to significant boiling or complete loss of coolant. Although the MTC and void reactivity coefficient at low void fractions are negative, the void coefficient at high void fraction can be positive for MOX fuel with high Pu content. Low-energy neutron capture resonances of ^{240}Pu and ^{242}Pu contribute negative reactivity to void coefficient at low void fractions (more neutrons are shifted towards these resonance energies). This is demonstrated in [Fig. 3](#), which shows the neutron spectrum in a typical LWR MOX fuel at different void fractions superimposed on the shape of neutron capture cross sections of ^{240}Pu and ^{242}Pu , as well as fission cross section

Fig. 3 Neutron flux spectrum at different void fractions (left axis) and cross sections of important Pu isotopes in a typical LWR MOX fuel.

of ^{239}Pu . At low void fractions, the magnitude of thermal flux spectrum is slightly reduced, while epithermal flux is increased. This leads to a loss of absorption in ^{239}Pu fission resonance, while increasing absorption in ^{240}Pu and ^{242}Pu capture resonances (**Fig. 3**), with an overall result being a loss of reactivity.

At high void fractions, the thermal neutron population diminishes, while neutron production in all U and Pu isotopes at high energies increases with spectrum hardening. If the reactivity of fully voided core is higher than the reactivity at nominal operating conditions, the safety case for such a core cannot be easily made without additional provisions for reactivity control in design basis accidents. Therefore, the Pu content in MOX fuel assemblies is typically restricted to below approximately 10%, which is still sufficient for achieving a cycle length comparable to UO_2 fuel with up to 5% enrichment. The limit on maximum Pu loading, however, depends on the fraction of ^{240}Pu and ^{242}Pu . Therefore, MOX fuel with Pu originating from high-burnup UO_2 fuel or Pu that has been recycled more than once (both of which typically have larger fraction of ^{240}Pu and ^{242}Pu) would have more a restrictive loading limit.

Pu isotopes have a slightly different distribution of fission product yields than uranium. The net effect of this is slightly higher parasitic absorption in MOX fuel fission products. This effect is partially compensated by the lower reactivity worth of ^{135}Xe because it is primarily a thermal neutron absorber and MOX fuel has significantly harder spectrum.

The final effect worth mentioning is the considerably lower effective delayed neutron fraction, β_{eff} , of ^{239}Pu compared to ^{235}U . It is lower by about a factor of two. This is a relatively minor issue. It should be considered in assessments of fast reactivity insertion accident scenarios (RIA) such as control rod ejection, main steam line break or boron dilution. Energy deposition in the fuel during a power excursion due to RIA is roughly proportional to the difference between the reactivity inserted and delayed neutron fraction. As the delayed neutron fraction is reduced, fuel energy deposition would increase and could potentially exceed the fuel damage limit. MOX fuel-loaded cores, however, are not substantially different from UO_2 fueled cores because, at the more limiting end of cycle (EOC) conditions, most of the power would be produced by fissions in Pu isotopes in both core types. Furthermore, the effect of a smaller β_{eff} in MOX fuel on the energy deposition in fast transients is more than offset by the stronger negative Doppler reactivity feedback, typically leading to more favorable behavior (even smaller energy deposition) in RIA than in UO_2 fuel cores. In general, power transients in a core with small β_{eff} would be more rapid and could impose some restrictions on the reactor control systems. This may become an issue if large quantities of MA with even smaller β_{eff} are recycled in addition to Pu.

Efficiency of recycling

As mentioned earlier, Pu and MA can be recycled in a variety of host matrices such as UO_2 (MOX fuel), ThO_2 or a range of fertile-free matrix materials. Therefore, the initial Pu and MA will not only be fissioned but may also be newly generated. The set of newly generated nuclides and the rate of their generation will obviously depend on the host matrix and other fuel and core design parameters.

Single-pass recycling of Pu and MA can have two competing objectives. On one hand, Pu can be considered a liability. Therefore, it is desirable to reduce its amount as fast as possible to avoid the risk of proliferation and/or cost of its storage, safeguarding and

final disposal. To achieve this objective (maximize Pu burning rate), recycled Pu fuel needs to be designed such that generation of new fissile plutonium, or the conversion ratio (CR), should be minimized.

On the other hand, Pu (or TRU) can be considered a valuable resource because of the cost and complexity of Pu (or TRU) extraction from used fuel and recycled fuel manufacturing. This will also increase the energy value of natural uranium from which the original fuel containing Pu to be recycled was manufactured. Therefore, there is a clear incentive for the energy recovered from the recycled Pu to be maximized. This can be achieved if the power produced by the secondary, in situ generated fissile isotopes, is as high as possible. This suggests that the CR should also be as high as possible in order to amplify the initial fissile material energy value. Efficient utilization of the recycled Pu (or TRU) would allow achieving high cumulative burnup per unit of initial fissile loading, which in LWRs, also minimizes the fraction of residual fissile material in the used fuel.

The most effective option for achieving the first objective is the use of a fertile-free fuel (FFF) because it has $CR = 0$, that is, every unit of energy produced by the fuel comes from fissioning the original Pu. The transmutation rate in FFF is determined solely by the core power and only slightly varies with initial TRU composition because of the small differences in energy release per fission and atomic mass of different TRU nuclides. For a typical value of about 200 MeV of energy released per fission, slightly over one metric ton of Pu or TRU can be burnt in one 1GW-electric PWR core loaded with FFF per one full power year of operation.

Numerous options for FFF have been proposed and studied (Pöml et al., 2012), but FFF remain a technology with relatively low maturity for it to be readily used in LWRs. Apart from lacking sufficient experience with manufacturing, irradiation performance data and a non-ideal combination of properties (such as thermal conductivity, melting point, radiation damage resistance etc.), FFFs pose a number of operational challenges to an LWR core design. The most important ones are a very large and typically non-linear reactivity loss with burnup resulting from low CR and greatly diminished Doppler reactivity feedback due to the absence of fertile nuclides. A large reactivity loss with burnup may lead to prohibitively high power peaking factors in a multi-batch core, while a reduced Doppler coefficient (DC) can result in excessive energy deposition in the fuel during fast reactivity transients which rely on Doppler Effect to limit the power excursion. Furthermore, for some combinations of TRU with their inert host matrices and burnable poisons, void coefficient of reactivity can become positive, which is another safety concern. These challenges, however, can be in principle mitigated by a careful choice of burnable absorbers and fuel assembly design (Fridman et al., 2007; Schwageraus et al., 2007).

In the case of Pu-UO₂ MOX, which is by far the most well-understood fuel form, the conversion ratio (generation of new Pu from ²³⁸U) is high but can be suppressed somewhat and Pu burning rate increased by varying the relative amount of fuel and moderator. Unfortunately, for a standard PWR fuel assembly geometry, the rate of Pu transmutation is approximately a factor 3 lower compared to FFF.

In order to address the issues related to harder neutron spectrum in Pu (or TRU) bearing fuels without changing the standard fuel geometry, using U-Pu-Zr hydride as a fuel form has been proposed (Ganda and Greenspan, 2009). Hydrogen atoms contained in the fuel provide additional moderation softening the neutron spectrum. As a result, reactivity of the fuel is increased allowing to achieve higher burnup and longer cycle. Alternatively, smaller Pu loading is required in hydride fuel than in MOX to achieve comparable fuel cycle length. In either case, larger fraction of initial Pu can be burnt. About half of the loaded Pu can be transmuted using hydride fuel form in a PWR fuel assembly with conventional design.

Thorium dioxide can serve as an attractive alternative fuel matrix for the transmutation of Pu and MA because it is a very stable fuel form with which we have reasonable experience and, more importantly, does not generate new Pu or MA. In terms of the Pu (or TRU) burning rate, Pu-Th MOX performs in between the Pu-U MOX and FFF, burning about 700 kg of Pu/GWe-Year in a typical PWR fuel assembly geometry (Table 1). It does, however, generate ²³³U and associated thorium transmutation chain nuclides which, similar to Pu and MA, are long-lived and represent a concern for long-term geological storage. If thorium transmutation chain nuclides are added to the total count of TRU mass, the net burning rate of actinides drops to values similar to those of traditional Pu-U MOX.

Th-Pu MOX has other advantages, however. For example, a higher loading of Pu (or TRU) is possible because of the less restrictive void reactivity coefficient (Kotlyar et al., 2017). Otherwise, Pu-Th MOX has very similar operational characteristics to those of traditional Pu-U MOX (Fridman and Kliem, 2011).

Uranium-233 generated from ²³²Th poses a proliferation concern as it is, in principle, a weapons-usable fissile material. It has been argued that because of contamination with trace amounts of ²³²U, which has very high energy photon emitters in its decay chain, ²³³U would be self-protected and can be considered proliferation resistant. However, this argument is not universally accepted in the non-proliferation community and often accompanied by an additional requirement for isotopic dilution (or denaturing) of newly bred ²³³U with ²³⁸U before fabrication of the fresh Pu-Th MOX fuel. The presence of ²³⁸U further deteriorates the Pu (or TRU) burning efficiency (Schwageraus et al., 2004).

Table 1 compares the single-pass Pu or TRU burning performance of the different fuel types discussed above if used in a typical PWR with a standard fuel assembly geometry and operational characteristics, such as core power density, discharge burnup and fuel cycle length.

The left-hand side of Fig. 4 shows TRU burning rates that can be achieved in Pu-Th MOX and FFF fuel if the constraint on fuel geometry (moderator to fuel volume ratio) is relaxed. The TRU burning rate in FFF is obviously insensitive to the fuel geometry, but in Pu-Th MOX, it can be improved somewhat by increasing the amount of moderator relative to the fuel.

With regards to achieving the second objective of maximum fractional TRU burnup, FFF fuel again has an advantage, as can be seen in Table 1, while UO₂- and ThO₂-based MOX fuels have practically identical performance if ²³³U is counted as TRU.

Table 1 Performance comparison of single-pass Pu and TRU recycling options in a PWR.

	UO ₂	Pu MOX	TRU MOX	Pu ThO ₂	TRU ThO ₂	TRU FFF
Discharge Burnup, MWd/kg	51	46	52	54	55	541
TRU generation rate, kg/GWe-Year	+260	−310	−480	−686	−793	−1150
Initial TRU, kg/assembly	0.0	32.5	74.8	42.8	100.5	48.4
Discharged TRU, kg/assembly	5.5	25.3	63.6	26.8	82.0	21.4
Fractional burnup: TRU	—	0.22	0.15	0.37	0.18	0.56
Fractional burnup: TRU + ²³³ U	—	0.22	0.15	0.25	0.14	0.56
Discharged Pu, kg/GWe-Year	237	152	179	122	173	82

**Fig. 4** Comparison of TRU transmutation efficiency in single-pass Pu-Th MOX and Fertile-free fuel.

The plot on the right-hand side of Fig. 4 demonstrates that a typical PWR fuel design is nearly the worst possible for ThO₂-based MOX, if the TRU burnt fraction is to be maximized. Note that each point along the plot lines has the same initial TRU loading but very different corresponding discharge burnup because the neutron spectrum is significantly affected by the amount of moderator available and so is the proportion of fissile versus fertile absorptions. Both FFF and ThO₂-based MOX can benefit from a softer spectrum because it generally results in higher reactivity during irradiation and, thus, a longer fuel cycle. However, a substantial increase in moderator volume would be impractical without detrimental effects on other operational and core performance characteristics.

Uranium savings and effect on repository

In order to operate a single full PWR core on recycled Pu or TRU fuel, multiple conventional UO₂ cores would be required to generate the necessary fissile material. It can be seen from Table 1 that Pu from about five conventional cores would need to be extracted to feed a single Pu-U MOX core. This so called “support ratio” for other fuel types is even higher, with over 18 conventional cores required to support a single TRU-ThO₂ MOX core. Furthermore, only marginal gains in terms of reducing the support ratio through alterations of fuel dimensions can be practical without negatively affecting the core performance in terms of safety or economics. As a result, the fuel savings achieved through single-pass recycling are relatively modest—on the order of 20% of natural uranium can be saved if single-pass Pu recycling is employed instead of direct disposal of used UO₂ fuel.

Used fuel characteristics relevant to geological disposal such as radiotoxicity and decay heat can be improved if the amount of actinides is reduced. However, this benefit is also marginal. Fig. 5 compares waste disposal characteristics of the fuel types presented in Table 1. The plot on the left-hand side of the figure presents the decay heat generation for actinides (no FP) from the used fuel normalized to total energy produced by the fuels. The energy for normalization includes both the conventional UO₂ cores and a TRU-loaded core they support. As evident from the figure, all fuel types are relatively close to each other and to the reference UO₂ case. The radiotoxicity of actinides in used fuel from Pu/TRU cores relative to those from UO₂ cores with an equivalent amount of energy output is compared in the right-hand side of Fig. 5. The radiotoxicity of actinides is not particularly important in the first hundred years or so because during this period, the used fuel characteristics are dominated by the FP. In the longer term, different options do offer some benefit, reducing the radiotoxicity by up to factor of 2–3 depending on the fuel option and time period of interest.

This reduction, however, was found to be insufficient to make a substantial difference to simplification of the safety or the costs of construction and operation of a geological repository. Instead, at least two orders of magnitude (factor of 100) reduction in loss rate of TRU from a fuel cycle into the repository is needed. Exceeding a 99% burnup fraction of TRU in a single-pass recycling is impractical to achieve. It can only be achieved if all TRUs are recycled indefinitely within either the same reactor fleet (e.g.,

Fig. 5 Comparison of decay heat and ingestion radiotoxicity for single-pass Pu/TRU burning options.

LWRs) or a fleet of dedicated TRU transmutation systems (e.g., critical or external neutron source-driven fast spectrum reactors) with only 0.1% of TRU mass allowed to be leaked to the waste streams due to inefficiencies in the reprocessing and fabrication stages (Van Tuyle and Finck, 2001). The allowable TRU loss rate is determined by the requirement to reduce the time taken for the radiotoxicity of used fuel to reach that of the natural uranium used for its fabrication from several hundred thousand to less than a thousand years.

Multi-recycling of Pu and MA in LWRs

As mentioned earlier in this chapter, the meaningful environmental benefits of a closed fuel cycle can only be realized if the following conditions are met:

- MA are recycled in addition to Pu;
- Pu and MA are not just recycled once, but kept within the fuel cycle indefinitely;
- TRU losses to the repository as a result of inefficiencies in recycling processes are kept below 0.1%.

These conditions pose several challenges to fuel cycle facilities, core design and reactor operation. This chapter will mostly focus on the latter. The challenges are mostly linked to the increasing amount of MA relative to Pu and the reduced fraction of fissile isotopes with the number of consecutive recycling stages (passes through the system).

Practically all the LWR operational challenges mentioned in the discussion of single-pass Pu recycling as MOX fuel, such as degradation in reactivity worth of reactivity control materials and restrictive void reactivity coefficient, are also relevant to TRU multi-recycling. Many of the issues, however, become progressively more severe. In fact, recycling of Pu as MOX beyond a second pass becomes impractical without modification of the fuel design.

The reduction in the relative fractions of fissile ^{239}Pu and ^{241}Pu in irradiated MOX fuel implies that if this Pu is further recycled, a higher Pu loading would be needed in the next recycle of MOX in order to maintain the same fuel cycle length and discharge burnup. It also implies that subsequent recycles of MOX fuel will have even higher fractions of ^{240}Pu and ^{242}Pu isotopes. As stated earlier, these are the isotopes responsible for the limit on Pu loading associated with the positive void reactivity effect.

The most fundamental challenge to feasibility of multi-recycling, however, even before considering any of the practicality issues mentioned above, is the ability of an LWR fleet to achieve steady state operation in which the total amount of TRU in the system is stabilized (zero net production of TRU). In order to achieve such a steady state, a sufficient amount of neutrons should be available in the system which, in addition to being able to maintain the criticality of the system for a reasonable time, can also be used to transmute TRU nuclides at the rate required to assure zero net production.

Some TRU nuclides are fissile in a thermal LWR spectrum and therefore produce on average a surplus of neutrons. Other TRU nuclides, however, are non-fissile in thermal spectrum and therefore require at least one or more neutron captures before they are converted into fissile nuclides and, eventually, into fission products.

It has been argued and generally accepted (Wigeland et al., 2021) that fast reactors are more efficient for the recycling and transmutation of TRU than LWRs (or thermal reactors in general). This is because the ratio of fission to capture reaction cross sections in most TRU is more favorable in a fast spectrum (see for example Fig. 5 in Shusterman, 2021) and the average number of neutrons released per fission is greater. In other words, more neutrons are available in the fast spectrum while fewer are required on average to transmute a relevant mix of TRU into short-lived fission products (Salvatores, 2002). Furthermore, the core physics of fast reactors is less sensitive to TRU isotopic mix, because practically all TRU isotopes are fissile, offering greater tolerance of the wide range of composition variations that result from multi-recycling.

The greater number of neutrons produced by fission in a fast spectrum is significantly offset by the high neutron leakage in fast reactors which typically have compact (high surface to volume ratio) cores to feature high neutron leakage probability in order to limit the magnitude of positive reactivity effect due to coolant thermal expansion or voiding—a major safety concern in sodium-cooled fast reactors.

LWRs too have an excess of neutrons during their operating cycle. This excess is typically compensated by various absorber materials (e.g., control rods, soluble and/or burnable poisons). It can be argued that, in a carefully designed LWR core, these excess neutrons can be used instead for transmutation of TRU. If the available excess of neutrons is insufficient for achieving the transmutation rate needed for zero net production of TRU, one solution is to boost the feed of fissile nuclides by using a slightly higher uranium enrichment. In this case, the trade-off to be assessed is the environmental benefits of zero net TRU production versus the costs of a higher enriched uranium feed.

Two basic alternatives can be imagined for achieving a zero TRU balance in an LWR fleet of reactors. One method is to dedicate certain regions in every reactor core to fuel containing TRU generated by the same core in previous cycles, while the rest of the core is loaded with conventional UO_2 fuel. In this case, the core physics behavior could still be dominated by the conventional UO_2 fuel and minimal modifications to the reactor system would be required.

The alternative is to accept the significant design modifications required to handle multi-recycled TRU-loaded fuel and operate a small number of dedicated LWRs with such a modified core design as net TRU burners. In this case, other reactors in the fleet can operate with conventional fuel with no modifications.

It has been shown in multiple studies that both options are viable and can, in principle, operate with a variety of fuel forms for recycled TRU, including but not limited to uranium or thorium-based MOX or FFF.

Pioneering work on Pu recycling in PWRs has been done in France as their nuclear program from its earliest days considered various options for stabilizing the Pu inventory as an alternative to, or in combination with, sodium-cooled fast reactors. For enabling multi-recycling of Pu and some MA, an Advanced Plutonium Assembly (APA) concept was proposed (Puill and Bergeron, 1997). It is schematically shown in the right-hand side of Fig. 6. The assembly consists of a combination of low-enriched UO_2 fuel pins and large annular Pu/TRU-bearing inert matrix fuel pins. Large amount of water around TRU pins allows better moderation to mitigate the spectrum hardening effects of MOX fuel and provides better cooling to accommodate the higher power generation. Furthermore, the fertile-free fuel matrix facilitates high transmutation efficiency (high burnup fraction of TRU) and, thus, helps keep the TRU inventory in the assembly at a minimum. It has been shown that a fleet of PWRs, of which only about 30–40% of cores (depending on whether only Pu or also MA are recycled) are fully loaded with APA fuel, can achieve zero net TRU production (Golfier et al., 2001).

Another option, also discussed in (Shwageraus, 2021), which has already attracted notable development effort and has promising performance characteristics, is a derivative of the Resource-renewable BWR concept (RBWR-TB/TB2) by Hitachi. It is a tight-pitch, high-void fraction BWR designed to maximize TRU transmutation efficiency (Hino et al., 2015). A smaller amount of

Fig. 6 PWR fuel assembly designs for Pu recycling. From Thomas JB (2002) Nuclear power plant types and the management of plutonium and minor actinides—In search of fuel cycle flexibility. *Comptes Rendus Physique* 3(7–8): 783–796.

moderator makes the neutron spectrum sufficiently hard so as to take advantage of fast neutron properties for transmutation such as a higher probability of fission relative to capture in all nuclides and a larger number of neutrons released per fission.

The RBWR-TB core has smaller aspect ratio (flatter) than a conventional ABWR core to increase the neutron leakage and mitigate the positive void reactivity effect typical of fast reactors. With increasing void fraction, the neutron spectrum becomes harder, while the core materials' cross-sections become smaller. This leads to higher neutron leakage and loss of reactivity, compensating for the positive void reactivity effect at high void fractions which is also a common feature of MOX fuel with high TRU content. The RBWR-TB fuel is axially heterogeneous and consists of a natural or depleted uranium oxide zone sandwiched between two fissile U-TRU MOX zones (Fig. 7). With increasing void fraction, neutron leakage from the fissile zones to the internal blanket (a neutron sink) and to the axial reflectors is enhanced, compensating for the positive reactivity effect of spectrum hardening, to provide a net negative void reactivity effect.

More exotic and less developed alternatives have also been proposed, for example, a BWR fuel in which the top third of the length, where the void fraction is high, is loaded with recycled TRU in non-fertile nitride form or as U-TRU MOX (Wallenius and Westlén, 2008). Zirconium cladding is replaced in the top third of the fuel length with hafnium which is a strong thermal neutron absorber. These design modifications also result in sufficiently hard neutron spectrum to operate such a reactor as a net TRU burner supporting a fleet of reactors with conventional fuel.

Operating a fleet of LWRs with considerably different characteristics has an advantage of limiting the complexities of handling TRU-containing fuel to only a fraction of the reactors in the fleet. If this fraction, however, is significant, it might be more convenient and cost-effective to operate a fleet of identical plants, all operating with recycled TRU fuel, provided that such fuel characteristics do not drastically deviate from those of conventional fuel and do not require major reactor design, operating procedures and safety case modifications.

The above requirements generated a range of fuel assembly concepts which can recycle TRU within the same core. The fuel assemblies would consist mostly of fuel pins with conventional, low-enriched UO_2 fuel and a small fraction of TRU containing pins. The TRU pins would contain Pu and MA from both UO_2 and TRU pins, generated in or leftover from the previous irradiation cycle respectively. In order to maintain the core characteristics as close to conventional UO_2 fuel as possible, while maintaining zero net generation of TRU, as a general rule, the transmutation efficiency (TRU fractional burnup per recycling pass) should be as high as possible. This will help minimize the TRU inventory in an assembly and mitigate undesirable effects from TRU on the core physics.

Examples of such heterogeneous fuel assembly concepts include CORAIL (COMbustible Recyclable A ILot—French for “recycled fuel island”) which uses U-TRU MOX pins for transmutation in an otherwise conventional PWR fuel assembly (Aniel et al., 2000). A schematic view of CORAIL PWR fuel assembly is shown in the left-hand side of Fig. 6. A similar design uses a different TRU host fuel matrix. The CONFU (Combined Non-Fertile and Uranium) fuel assembly uses an inert matrix fuel (Shwageraus et al., 2005a). Due to the superior transmutation efficiency of FFF, i.e., no new TRU generation in TRU pins, the inventory of Pu and MA in the CONFU assembly is notably smaller than in the CORAIL assembly.

Thorium oxide can also be used as a matrix for TRU, achieving stabilization of the TRU inventory after several recycling passes (Shwageraus et al., 2005b). The inventory of TRU per assembly is comparable to CORAIL, if ^{233}U is recycled into UO_2 rather than ThO_2 pins, but higher than in CONFU. Other conceptual studies showed that the TRU inventory can also be stabilized in other heterogeneous arrangements (Lindley et al., 2014) or in a homogeneously mixed tertiary U-Th-TRU MOX fuel. In the latter case, all pins within a fuel assembly would have a uniform composition, i.e., no dedicated TRU bearing pins (Fridman et al., 2006).

All of the above concepts share a number of features. They all operate in a typical PWR environment with a thermal neutron spectrum. Therefore, the fissile content of the TRU isotopic vector progressively deteriorates with the number of recycling passes.

Fig. 7 Schematic view of RBWR-TB (Transuranics Burner) fuel assembly. Courtesy of Hitachi Ltd. 2020 with permission.

It takes multiple recycles for the most important isotopes to approach equilibrium. The concentration of some isotopes continues growing because of their small absorption cross section. The fuel cycle length is reduced with a deteriorating fissile quality of TRU, but this saturates after only about 3–4 recycling passes at a value about 10% lower than the reference conventional UO₂ fuel. It means that a similar fractional increase in feed uranium enrichment would be needed to compensate for that fuel cycle length reduction.

These studies have also found that these conceptual fuel assembly designs exhibit similar characteristics to those of traditional UO₂ fuel, meaning that no major changes to core design, reactor operation and safety case would be required.

The main challenges with multi-recycling of TRU are therefore associated with operation of fuel cycle facilities—not the reactor fleet. With the evolving TRU isotopic vector, the decay heat and radiation dose from the recycled TRU generally increase. This is due to the accumulation of relatively short-lived isotopes such as ²³⁸Pu, ²⁴¹Am, ²⁵²Cf and Cm isotopes with a high decay rate and associated emission of α -particles, high-energy photons or neutrons. These isotopes are very difficult to handle because of the cooling and radiation shielding requirements, which may become prohibitively expensive or even make the reprocessing and fabrication of TRU pins technically unfeasible.

Some of the isotopes, such as ²⁴²Cm ($T_{1/2} = 162.7$ days), ²⁴⁴Cm ($T_{1/2} = 18.1$ years) and ²⁵²Cf ($T_{1/2} = 2.64$ years), are sufficiently short-lived that longer cooling times can partially mitigate these challenges allowing a greater number of recycles in a given fuel cycle infrastructure. Fig. 8 compares the neutron source from spontaneous fission in TRU from CONFU fuel recycled using different cooling periods between fuel discharge and reprocessing. If the cooling is increased from 7 to 20 years, the spontaneous fission source is reduced to the levels comparable to conventional Pu MOX fuel routinely handled commercially.

An additional challenge is the technical feasibility, efficiency and cost of TRU chemical separation processes which must only allow < 1% TRU loss to the repository. A vast international R&D effort has already been invested in this area and many promising candidate processes have been identified for commercial application. Review of these techniques is presented in (Miguirditchian, 2021).

Summary

This chapter presented a brief overview of the conventional once-through (open) fuel cycle and discussed incentives for transitioning to a closed one while still using existing or evolutionary LWRs.

Partially closing the fuel cycle is possible by only recycling Pu or Pu and MA in LWR cores only once. The strategy of single-pass Pu recycling is already well-established in many countries with multiple available commercial scale facilities. All aspects of reactor design and operation as well as those of the associated fuel cycle infrastructure are well-understood. However, the benefits of such single-pass recycling for increase in uranium resource utilization, or for reduction in the radiotoxicity of fuel cycle waste products are marginal. This is because Pu from multiple conventional UO₂ fuel LWR cores is needed to feed a single MOX core while the net burnup of Pu in MOX fuel is small.

Studies investigating alternative fuel matrices for single-pass Pu or TRU recycling such as ThO₂ or Fertile-free Fuels arrived at similar conclusions for similar reasons.

Radiotoxicity of used LWR fuel reduces with time. It reaches the point at which it is equal to radiotoxicity of the originally mined uranium used to manufacture it after several hundred thousand years. It has been shown that in order to shorten this time to less than a thousand years, the fraction of TRU which is allowed to be lost to the repository in addition to fission products should be less than 0.1%. This is possible only if TRU are kept within the fuel cycle (recycled) indefinitely and chemical processes are available to deliver such a TRU separation efficiency.

Fig. 8 Effect of cooling time on Spontaneous Fission Source of recycled TRU fuel. From Shwageraus E, Hejzlar P, and Kazimi MS (2005a) A combined non-fertile and UO₂ PWR fuel assembly for actinide waste minimization. *Nuclear Technology* 149(3): 281–303.

Indefinite TRU recycling is easily achievable in fast spectrum reactors due to abundance of neutrons available for transmutation and the fact that fewer neutrons are required for TRU conversion to short-lived fission products.

Indefinite recycling in LWRs, however, is more challenging. It is possible by either developing fuel designs with a sufficiently hard neutron spectrum or supplementing the neutrons required for transmutation in thermal spectrum by slightly increasing the enrichment of the uranium used as a driver fuel. Several relatively mature designs exist for both options such as Hitachi's RBWR-TB or the CORAIL PWR fuel concept and their derivatives. A significant body of knowledge has been generated from these studies, suggesting that TRU recycling in LWRs is feasible—that is, a closed fuel cycle with zero net generation of TRU using well-established and well-understood LWR technology can be achieved.

The limiting issue remains the development of fuel cycle infrastructure capable of handling multiple TRU recycling passes. Changes in the TRU isotopic vector lead to increasing radiation shielding and cooling requirements which complicate practically all fuel cycle operations associated with recycling, manufacturing and transportation of TRU fuel. Allowing a greater cooling period between used fuel discharge and reprocessing operations can somewhat mitigate these challenges.

It appears that technological feasibility of a closed LWR fuel cycle is not the reason for lack of progress in implementing it. The relatively slow growth of nuclear power over recent decades and advances in geology and extraction technologies of natural uranium diminish the economic incentive for used LWR fuel recycling. The non-economic incentive of preserving a valuable energy resource for future generations is also not seen as sufficiently compelling. Furthermore, the environmental benefits of closed fuel cycle are difficult to quantify in monetary terms because of the time scale of the radioactive waste isolation problem, but it is still important for each generation to internalize its industrial waste instead of leaving it to future generations. Therefore, it can be argued that pursuing the closed fuel cycle is the ethically responsible choice for modern society, even at the expense of somewhat higher economic costs.

Acknowledgments

Introduction

In principle there are numerous options for nuclear fuel and fuel cycles based on the underlying nuclear physics. Research and development (R&D) of various nuclear fuel and fuel cycle options has been ongoing over the past 80 years, with many implementing technologies being explored. Today, fuel cycles and new technologies are being proposed and developed for a variety of purposes, including more efficient use of fuel resources, higher thermal efficiency, waste reduction, and lower capital and operating costs. The U.S. Department of Energy, Office of Nuclear Energy (DOE-NE) has been conducting R&D on a range of nuclear fuel and nuclear fuel cycles, guided by past studies and ongoing research. (US Department of Energy, 1980, 2002, 2008; International Atomic Energy Agency, 1980, 2009; Los Alamos National Laboratory, 2001; Massachusetts Institute of Technology, 2003, 2010; Wigeland et al., 2009, 2010).

All of these previous studies are constrained in some manner, either by the scope and consistency of the criteria used for evaluating different fuel cycles or by the range of fuel cycles considered, and as such are of limited use. To address the need for complete information to support R&D decisions, a study was conducted which reflected both the broad range of issues relevant to the present time and that examined a comprehensive range of fuel cycle options. This chapter briefly describes the scope of this comprehensive study, the methodology it used including the Evaluation Criteria, and selected findings regarding the benefits from and challenges in the implementation of the different fuel cycle options.

The nuclear fuel cycle evaluation and screening study

In late 2011, the U.S. Department of Energy, Office of Nuclear Energy (DOE-NE) chartered a new study on the identification and analysis of nuclear fuel cycle options, referred to as the Evaluation and Screening Study (E&S Study), to provide information about the potential benefits and challenges of nuclear fuel cycle options and, if possible, to identify a relatively small number of promising

* Retired.

fuel cycle options with the potential for achieving substantial improvements compared to the current nuclear fuel cycle in the United States (US Department of Energy, 2011b). The E&S Study defined the nuclear fuel cycle as shown in Fig. 1, which shows the components of a nuclear fuel cycle.

In the E&S Study Charter, criteria were specified to be used for evaluation of each fuel cycle option. The E&S Study was part of a larger effort to achieve Objective 3 “Develop sustainable nuclear fuel cycles” in the DOE Nuclear Energy Research and Development Roadmap (US Department of Energy, 2010), and followed the pilot demonstration of an evaluation and screening process (US Department of Energy, 2011a). The E&S Study addressed feedback from internal and external reviews of the pilot demonstration which identified the required areas of refinement and improvement of the process (US Government Accountability Office, 2011). A complete description of the E&S Study, including all results and analyses, is available in the final report for the study (Wigeland et al., 2014). A subsequent report discusses further details concerning minor actinide recycle (Wigeland, 2015). The final report on the E&S Study is available at: www/fuelcycleevaluation.inl.gov/SitePages/Home.aspx.

The evaluation and screening software (the Evaluation and Screening Tool, SET) and metric data are also available for download and use on the website, allowing exploration of any desired combination of metrics and criteria by any interested individuals.

Fuel cycle Evaluation Criteria

The E&S Study Charter (US Department of Energy, 2011b) specified nine Evaluation Criteria representing broadly-defined economic, environmental, safety, non-proliferation, security and sustainability goals to identify promising fuel cycle options and measure improvements as compared to the current nuclear fuel cycle in the United States. The first six criteria are related to the potential for benefit and the last three reflecting the challenges for developing and deploying a new fuel cycle.

Nine DOE-specified Evaluation Criteria

- Nuclear Waste Management (Study considered waste generation only)
- Proliferation risk
- Nuclear material security risk
- Safety
- Environmental impact
- Resource utilization
- Development and deployment risk
- Institutional issues
- Financial risk and economics

Nuclear Waste Management Criterion—Some nuclear fuel cycles may generate less waste than others, but all fuel cycles create similar wastes, both low-level and high-level radioactive wastes. Consequently, all nuclear fuel cycles require waste disposal capabilities, including the need for long-term isolation of some wastes. As a result, the E&S Study focused on the quantity and characteristics of the radioactive wastes generated by the different fuel cycles, including the current U.S. fuel cycle, not on the details of waste disposal such as geologic disposal environments.

Proliferation Risk Criterion—In general, assessing proliferation risk is a complex and challenging endeavor, primarily because it involves both technical and socio-political considerations, with the dominant factor being facility location. Since most of these factors are beyond the scope of the E&S Study, efforts focused only on evaluation of technical differences between fuel cycle options at the physics-based functional level that may influence proliferation risk (this study did not consider any specific implementing technologies as described in the following section).

Fig. 1 The Nuclear Energy System, also known as the Nuclear Fuel Cycle.

Nuclear Material Security Risk Criterion—The E&S Study could only inform on the materials available from the fuel cycle that would require physical protection. The other aspects of physical protection relevant to nuclear material security risk are a function of specific facility designs and operations, including physical barriers and assumptions made about the protective force and adversary force capabilities. These were not considerations in the E&S Study of fuel cycles.

Safety Criterion—The E&S Study considered whether a fuel cycle could be safely deployed and the relative challenges in addressing safety hazards for an alternative fuel cycle in comparison to the current U.S. fuel cycle for all of the facilities required for each fuel cycle. The E&S Study did not consider general questions on the acceptability of the current safety of nuclear power as deployed in the U.S.

Environmental Impact Criterion—The E&S Study considered the environmental impacts from the routine operations of a nuclear fuel cycle focusing on impacts from fuel acquisition and nuclear power generation. Environmental impacts from accidents at fuel cycle facilities are not included in this criterion since these are part of the Safety criterion. Similarly, the E&S Study did not consider the environmental impacts of waste disposal under this criterion since they are represented, directly or indirectly, in the Nuclear Waste Management criterion. The information in the E&S Study is only about the relative changes in such impacts between fuel cycle options, and not about whether such impacts are ultimately acceptable.

Resource Utilization Criterion—The E&S Study only considered the natural resources required for nuclear fuel (i.e., uranium and thorium), not resources in general.

Development and Deployment Risk Criterion—The E&S Study considered technology development needs for fuel cycle options including what would be necessary for maturing the technologies and factors that would affect deployment of a first-of-a-kind facility and integration of all parts of the entire fuel cycle.

Institutional Issues Criterion—The E&S Study considered issues such as the existing infrastructure, current regulations, and market conditions and any different supporting needs that alternative fuel cycles would have as potential challenges to the deployment of a fuel cycle.

Financial Risk and Economics Criterion—The E&S Study considered the relative differences in financial risk and economics among nuclear fuel cycle options. However, the E&S Study did not consider the overall economic viability of nuclear power in the U.S.

Evaluation Metrics

Evaluation Metrics were developed for the nine specified Evaluation Criteria, coordinated with input from DOE, industry, universities, and others through collaborations, meetings and reviews, as directed by the Study Charter. This activity resulted in one or more Evaluation Metrics for each Evaluation Criterion along with the justification for each metric and the methods to be used to calculate or estimate the metrics (Wigeland et al., 2014).

Table 1 shows the Evaluation Metrics for the nine Evaluation Criteria. The first six Criteria represented opportunities for improvement (or “benefit”) when compared to the current U.S. fuel cycle, while the other three are related to the “challenges” associated with developing and implementing any new fuel cycle. As a consequence, the current U.S. fuel cycle would likely perform best for the “challenge” criteria relating to development and deployment since this fuel cycle is already in use, with the exception of spent nuclear fuel (SNF) disposal, but it should be noted that disposal capabilities such as those required for SNF are needed by all fuel cycles for managing SNF and high level waste (HLW).

The possible data range for each Evaluation Metric was divided into sub-ranges, called data “bins”, with the result for each Evaluation Metric being a data bin value rather than a specific numerical value. This approach enabled a comprehensive assessment of all possible fuel cycles by removing the need for detailed specification of every part of a fuel cycle.

Comprehensive set of fuel cycle options

To allow the development and performance comparison of the comprehensive set of fuel cycle options, the E&S Study analyzed, evaluated, and screened nuclear fuel cycles only at what is termed the “functional” level, using the fundamental physics characteristics of each step in a fuel cycle (i.e., the physics principles defining what happens at each fuel cycle step, not the technologies for how a step is accomplished), resulting in a “technology-neutral” assessment. For example, a pressurized-water reactor (PWR) is a specific technology for implementing the function of thermal neutron irradiation. Similarly, reprocessing using PUREX to isolate and recover uranium and plutonium is a specific technology for implementing the function of recovering uranium and plutonium from irradiated fuel for reuse. For the E&S Study to be comprehensive in consideration of the relative performance of all possible fuel cycles, the E&S Study only evaluated fuel cycle options using such functions as thermal neutron irradiation, or reprocessing to recover uranium and plutonium, and did not evaluate or screen either specific technology options or implementation/deployment options.

Representing the comprehensive set of fuel cycle options with a finite set of groups

- Although there can be an almost endless set of fuel cycle options when all technology and fuel cycle option choices are considered, there is only a relatively smaller set of fuel cycle option groups based on fundamental physics principles.
- Defining the finite set of groups requires consideration only of the physics principles.
- Accounting for the similarities among options, 40 distinct groups were identified as sufficient to represent possible fuel cycle options for the Evaluation Criteria specific to this study.

Table 1 Evaluation Criteria and Evaluation Metrics.

<i>“Benefit” Criteria</i>	
Nuclear Waste Management	Mass of SNF + HLW disposed per energy generated
	Activity of SNF + HLW (@100 years) per energy generated
	Activity of SNF + HLW (@100,000 years) per energy generated
	Mass of DU + RU + RTh disposed per energy generated ^a
	Volume of LLW per energy generated
Proliferation Risk	Material attractiveness—normal operating conditions
	Material attractiveness—normal operating conditions
Nuclear Material Security Risk	Activity of SNF + HLW (@10 years) per energy generated
	Challenges of addressing safety hazards
Safety	Safety of the deployed system
	Land use per energy generated
	Water use per energy generated
	Radiological exposure—total estimated worker dose per energy generated
Environmental Impact	Carbon emission—CO ₂ released per energy generated
	Natural Uranium required per energy generated
Resource Utilization	Natural Thorium required per energy generated
<i>“Challenge” Criteria</i>	
Development and Deployment Risk	Development time
	Development cost
	Deployment cost from prototypic validation to FOAK commercial
	Compatibility with the existing infrastructure
	Existence of regulations for the fuel cycle and familiarity with licensing
	Existence of market incentives and/or barriers to commercial implementation of fuel cycle processes
	Compatibility with the existing infrastructure
	Existence of regulations for the fuel cycle and familiarity with licensing
Institutional Issues	Existence of market incentives and/or barriers to commercial implementation
Financial Risk and Economic	Levelized Cost of Electricity at Equilibrium

^aDU, RU, and RTh are depleted uranium, recovered uranium, and recovered thorium, respectively.

Fundamental fuel cycle characteristics

The definition of a nuclear fuel cycle used in the E&S Study begins with mining, and ends with the generation of wastes requiring disposal.

The study considered the entire possible range for each physics principle, including once-through and recycle fuel cycles; thermal, intermediate and fast neutron reactors; critical and sub-critical (externally-driven systems, or EDS) reactors; and uranium and/or thorium for natural fuel resources, along with other distinguishing fuel cycle features. All possible combinations of the physics principles resulted in the comprehensive set of possible fuel cycles, as follows:

1. “Once-Through” or “Recycle” where recycle includes limited recycle and continuous recycle
 - Limited recycle fuel cycles are those that recycle only once or a limited number of times before SNF is disposed along with high level waste generated from the recycle processes
 - Continuous recycle fuel cycles are those that always reprocess irradiated fuel for recycle and only high-level waste (HLW) is disposed
2. Irradiation system
 - Self-sustaining (critical reactor)
 - Externally-driven (sub-critical reactor)
3. Neutron spectrum (as defined in Appendix B of [Wigeland et al. \(2014\)](#))
 - Thermal
 - Intermediate
 - Fast
4. Nuclear fuel
 - Uranium
 - Thorium and thorium/uranium
5. Isotopic enrichment
 - Uranium enrichment
 - No Uranium enrichment
6. Recycled elements
 - One or more of the following: U (includes ²³³U bred from Th); Pu; minor actinides (MA); All transuranic elements (TRU); Th; fission products (FP)

The permutations of these functional characteristics resulted in about 4400 potentially viable Fuel Cycle Option Groups. Starting with this set of Fuel Cycle Option Groups, many of these groups were combined using a series of operations based on the similarity of their expected physics-based performance with respect to the Evaluation Criteria (discussed in Wigeland et al. (2014)), such as waste generation or resource use, with the principle of ensuring that promising options would be identified by the Evaluation and Screening, but that no promising option would be inadvertently screened out by being placed in a lesser performing Evaluation Group. At the end of this process, 40 groups of fuel cycles called Evaluation Groups were obtained that provide a comprehensive representation of the performance of all possible nuclear fuel cycles to inform on their potential for providing substantial improvement to the current U.S. fuel cycle:

- 8 Once-through Evaluation Groups
- 10 Limited recycle Evaluation Groups
- 22 Continuous recycle Evaluation Groups

Even though the fuel cycles were collected based on similarity of physics-based performance, the overall performance would not necessarily be equal for all fuel cycles in an Evaluation Group. Since the fuel cycles collected within each Evaluation Group potentially span a range of overall performance, it was recognized that some of the collected fuel cycles in each Evaluation Group may actually be relatively poorer performers overall when compared to the best fuel cycles in the group. To appropriately inform on the potential of each group, the best performance potential for each Evaluation Group and each Evaluation Metric was evaluated, as described in Wigeland et al. (2014), even though all members of the Group would not necessarily be able to achieve such performance. Table 2 contains short descriptions of the 40 Evaluation Groups indicative of the fuel cycle options included in each group, but are not complete descriptions of the Evaluation Group in most cases; see the final report for complete details (Wigeland et al., 2014). Evaluation Group EG01 served as the “Basis of Comparison,” representing the current U.S. fuel cycle.

Best performance potential of each evaluation group

“Analysis Examples,” were developed for each Evaluation Group by specifying the technical functions and specifications of the irradiation environment for a representative fuel cycle in a Fuel Cycle Option Group in each Evaluation Group to provide an example that represents the focus of the Evaluation Group, e.g., specifying a PWR as the thermal reactor in a fuel cycle. The Analysis Example was used for calculating detailed reactor physics-based material mass balance information and other information as appropriate for determining the result for each Evaluation Metric, i.e., which data bin represented the Analysis Example performance.

The results were reviewed to determine if any characteristic of the Analysis Example resulted in performance that could be less than the best performance for all fuel cycles in the Evaluation Group, and revised if necessary. (Wigeland et al., 2014).

Evaluation Criteria weighting scenarios

Following completion of the determination of the Evaluation Metrics, the performance comparison between the Evaluation Groups was conducted. Eleven multiple-criteria scenarios were created to represent a variety of different perspectives about the relative importance (weight, or tradeoff factor) of changes in four of the six benefit criteria (Nuclear Waste Management, Resource Utilization, Environmental Impact, and Safety) and to investigate the sensitivity of the results to changes in those perspectives. The scenarios were grouped into three categories:

- Scenario 1—Changes in the four listed benefit criteria were of equal importance.
- Scenarios 2 through 5—These four scenarios each emphasized changes in a single benefit criterion with respect to a balance of the three remaining criteria.

Six other scenarios were defined, each exploring an emphasis on a sub-set of these four benefit criteria, each defined to reflect one of a variety of perspectives. These scenarios were defined as:

- Scenario 6—emphasize the importance of differences between Evaluation Groups on the Nuclear Waste Management, Resource Utilization, and Environmental Impact criteria—to emphasize the importance of differences in the physical impacts of producing nuclear power and the potential to reduce the impacts by choice of fuel cycle.
- Scenario 7—de-emphasize the importance of differences between Evaluation Groups on the Environmental Impact criterion, focusing instead on the potential for improvement in Nuclear Waste Management, Resource Utilization, and Safety Criteria based on choice of fuel cycle.
- Scenario 8—de-emphasize the importance of differences between Evaluation Groups on the Resource Utilization criterion—to explore the potential impact of expanded fuel resource availability (such as uranium from seawater) and its effect on the relative benefits of fuel cycles. This scenario also provides insight on whether Resource Utilization as a separate criterion adds a different perspective to the results.

Table 2 The 40 Evaluation Groups.

<i>Evaluation Group</i>	<i>Short Description Indicative of Fuel Cycles in the Evaluation Group (Detailed Description of Each Evaluation Group is in Appendix B of Wigeland et al. (2014))</i>
<i>Once-through</i>	
EG01	Once-through using enriched-U fuel in thermal critical reactors
EG02	Once-through using enriched-U fuel to high burnup in thermal or fast critical reactor
EG03	Once-through using natural-U fuel in thermal critical reactors
EG04	Once-through using natural-U fuel to very high burnup in fast critical reactors
EG05	Once-through using enriched-U/Th fuel in thermal or fast critical reactors
EG06	Once-through using Th fuel to very high burnup in thermal EDS
EG07	Once-through using natural-U fuel to very high burnup in thermal or fast EDS
EG08	Once-through using Th fuel to very high burnup in fast EDS
<i>Limited Recycle</i>	
EG09	Limited recycle of U/TRU with new natural-U fuel to very high burnup in fast critical reactors
EG10	Limited recycle of $^{233}\text{U}/\text{Th}$ with new Th fuel in fast and/or thermal critical reactors
EG11	Limited recycle of $^{233}\text{U}/\text{Th}$ with new enriched-U/Th fuel in fast or thermal critical reactors
EG12	Limited recycle of U/Pu with new natural-U fuel in fast and/or thermal critical reactor
EG13	Limited recycle of U/Pu with new enriched-U fuel in thermal critical reactor
EG14	Limited recycle of U/Pu with new natural-U fuel in both fast and thermal critical reactors
EG15	Limited recycle of U/Pu with new enriched-U fuel in both fast and thermal critical reactors
EG16	Limited recycle of U/Pu with new enriched-U fuel in thermal critical reactors and fast EDS
EG17	Limited recycle of Pu/Th with new enriched-U/Th fuel in thermal critical reactors
EG18	Limited recycle of $^{233}\text{U}/\text{Th}$ with new enriched-U/Th fuel in thermal critical reactors
<i>Continuous Recycle</i>	
EG19	Continuous recycle of U/Pu with new natural-U fuel in thermal critical reactors
EG20	Continuous recycle of U/TRU with new natural-U fuel in thermal critical reactors
EG21	Continuous recycle of U/Pu with new enriched-U fuel in thermal critical reactor
EG22	Continuous recycle of U/TRU with new enriched-U fuel in thermal critical reactors
EG23	Continuous recycle of U/Pu with new natural-U fuel in fast critical reactors
EG24	Continuous recycle of U/TRU with new natural-U fuel in fast critical reactor
EG25	Continuous recycle of $^{233}\text{U}/\text{Th}$ with new enriched-U/Th fuel in thermal critical reactors
EG26	Continuous recycle of $^{233}\text{U}/\text{Th}$ with new Th fuel in thermal critical reactors
EG27	Continuous recycle of $^{233}\text{U}/\text{Th}$ with new enriched-U/Th fuel in fast critical reactors
EG28	Continuous recycle of $^{233}\text{U}/\text{Th}$ with new Th fuel in fast critical reactors
EG29	Continuous recycle of U/Pu with new natural-U fuel in both fast and thermal critical reactors
EG30	Continuous recycle of U/TRU with new natural-U fuel in both fast and thermal critical reactors
EG31	Continuous recycle of U/Pu with new enriched-U fuel in both fast and thermal critical reactors
EG32	Continuous recycle of U/TRU with new enriched-U fuel in both fast and thermal critical reactors
EG33	Continuous recycle of U/Pu with new natural-U fuel in both fast EDS and thermal critical reactors
EG34	Continuous recycle of U/TRU with new natural-U fuel in both fast EDS and thermal critical reactors
EG35	Continuous recycle of U/Pu with new enriched-U fuel in both thermal critical reactors and fast EDS
EG36	Continuous recycle of U/TRU with new enriched-U fuel in both thermal critical reactors and fast EDS
EG37	Continuous recycle of $^{233}\text{U}/\text{Th}$ with new enriched-U/Th fuel in both fast and thermal critical reactors
EG38	Continuous recycle of $^{233}\text{U}/\text{Th}$ with new Th fuel in both fast and thermal critical reactors
EG39	Continuous recycle of $^{233}\text{U}/\text{Th}$ with new enriched-U fuel in both thermal critical reactors and fast EDS
EG40	Continuous recycle of $^{233}\text{U}/\text{Th}$ with new Th fuel in fast EDS and thermal critical reactors

Note: EDS = externally-driven systems (subcritical reactors), and $^{233}\text{U}/\text{Th}$ indicates recycle of uranium that is predominantly ^{233}U with thorium.

- Scenario 9—de-emphasize the importance of differences between Evaluation Groups on the Nuclear Waste Management criterion—to explore, in combination with Scenarios 1, 7 and 8, any potential overlap between the Nuclear Waste Management and the Resource Utilization criteria and the potential impact on the choice of fuel cycle.
- Scenario 10—emphasize the importance of differences between Evaluation Groups on the Nuclear Waste Management and Resource Utilization criteria—to focus on long-term and large-scale sustainability issues and the potential impact of the choice of fuel cycle.
- Scenario 11—emphasize the importance of differences between Evaluation Groups on the Nuclear Waste Management and Safety criteria—to explore a perspective reflecting the most prominent current concerns and the potential impact of the choice of fuel cycle.

The same process was used to identify the potentially promising Evaluation Groups for each scenario and for all scenarios. The performance improvement of the Evaluation Groups provided information on the benefit potential for each scenario. As with the criteria, an additional step related the potential improvement in performance for the benefit criteria with the challenge of developing and deploying the fuel cycle, as represented by the Development and Deployment Risk criterion. The sensitivity of the

identification of the promising Evaluation Groups to the range of value judgments was explored by subsequent parametric variation of the functions and tradeoff factors, ultimately resulting in the sets of promising Evaluation Groups (Wigeland et al., 2014).

Key results on relative fuel cycle performance

The E&S Study final report (Wigeland et al., 2014) provides performance data for the 40 Evaluation Groups of fuel cycles on the 25 Evaluation Metrics, the nine Evaluation Criteria, and for 11 multiple-criteria Scenarios, assigning varying degrees of relative importance to the changes possible for each criterion to explore a potential range of policy guidance. The Evaluation Groups were identified where improvement with respect to the current U.S. fuel cycle is possible. Recognizing that what constitutes a “substantial improvement” as stated in the Study Charter is a judgment that may vary considerably among decision-makers, the report identifies multiple sets of potentially promising Evaluation Groups based on the amount of improvement. Using this approach, decision-makers can find the appropriate promising Evaluation Groups corresponding to their view of what constitutes a substantial level of improvement. The report also provides the corresponding development and deployment challenges for all Evaluation Groups, allowing decision-makers to consider both the potential benefits and the associated challenges. The report then identifies the associated R&D that would be required to develop the fuel cycles in the promising Evaluation Groups.

For the six benefit criteria from a fuel cycle alternative to the current U.S. fuel cycle, the alternative fuel cycles were evaluated by comparing them to the current U.S. fuel cycle assuming successful implementation of all disposal paths, and identified several promising Evaluation Groups that have the potential for improved performance relative to the current U.S. fuel cycle for the six benefit criteria as follows:

- *Nuclear Waste Management Criterion:* On a per unit energy generated basis, reduction in generation of fuel cycle waste materials requiring geologic disposal by as much as a factor of 10 or more, reduction in long-term activity corresponding to a reduction in long-term radiation hazard by as much as a factor of 10 or more, and reduction in uranium (depleted from the enrichment process or recovered from reprocessing) and/or thorium (recovered from reprocessing) disposal needs by a factor of 100 or more, and without a large increase in low-level waste generation (up to about 50% higher).
- *Resource Utilization Criterion:* On a per unit energy basis, reduction in the amount of fuel resources needed by a factor of 100 or more.
- *Environmental Impact Criterion:* On a per unit energy basis, reduction in the amount of land required and in the amount of CO₂ emitted (always much lower for nuclear power than for fossil-based generation) by about a factor of 2.
- *Proliferation Risk Criterion:* All of the Evaluation Groups were evaluated as capable of being comparable to the current U.S. fuel cycle at the physics-based functional level as far as material attractiveness is concerned.
- *Nuclear Material Security Risk Criterion:* All of the Evaluation Groups were assessed as comparable to the current U.S. fuel cycle at the physics-based functional level as far as material attractiveness for usefulness in improvised nuclear devices (INDs) is concerned. All Evaluation Groups also contain highly radioactive spent fuel and/or HLW, providing targets with activity comparable to the current U.S. fuel cycle in usefulness for radiation dispersal devices (RDDs)/radiation exposure devices (REDs).
- *Safety Criterion:* It was concluded that it would be possible to safely deploy at least one of the fuel cycles in each Evaluation Group. It was also concluded that the ability to provide enhanced safety compared to the current U.S. facilities was not affected by the choice of fuel cycle but depended on decisions that would be made for implementing the fuel cycle, such as technology choices and facility design decisions.

For the three Evaluation Criteria related to the challenge of developing and deploying a fuel cycle alternative to the current U.S. fuel cycle, the following summarizes the challenges identified by the Study:

- *Development and Deployment Risk:* Alternatives to the current U.S. fuel cycle in the promising Evaluation Groups require R&D to bring the enabling technologies up to the level of successful engineering demonstration, including pilot-scale facilities, estimated as requiring several billion dollars over 10–25 years. Similarly, further development up to the first-of-a-kind commercial facilities were estimated to require an additional several billion dollars. Any transition to a new fuel cycle would take decades to achieve, although some fuel cycle performance benefits such as wastes destined for deep geologic disposal could accrue more quickly. Fully deploying an alternative fuel cycle would likely require several hundred billion dollars or more, comparable to the cost of continuing with the current U.S. fuel cycle as new reactors replace existing reactors.
- *Institutional Issues:* Any of the alternative fuel cycles in the promising Evaluation Groups faces several institutional issues, including lack of supporting infrastructure, lack of regulations and licensing experience, and market barriers to commercial implementation.
- *Financial Risk and Economics:* Estimates of the electricity production cost for fuel cycles in the most promising Evaluation Groups and many of the promising Evaluation Groups are similar to, or close to, those for continuing with the current U.S. fuel cycle.

Promising fuel cycles for performance improvement

Promising fuel cycle options were defined as those that offer the potential for significant improvement over the currently deployed fuel cycle in the United States. Different fuel cycle options might be considered promising by decision-makers or stakeholders who

have different priorities or values. A wide range of perspectives was used to represent this variability in decision-maker preferences, and the sensitivity analyses for each scenario identified Evaluation Groups that are robust to different perspectives, i.e., those that exceed the promise threshold for many of the perspectives considered. The promising options were organized into three sets: most promising options, additional potentially promising options, and other potentially promising options.

An example of the results is shown in Fig. 2 for the scenario where the four benefit criteria of Nuclear Waste Management, Resource Utilization, Environmental Impact, and Safety were given equal criteria tradeoff factors. The potential for improved performance is represented by a non-dimensional benefit utility on the y-axis, and the relative challenge of development and deployment of fuel cycles providing this improved performance is represented by a non-dimensional utility on the x-axis. As the arrows on Fig. 2 indicate, higher utility on the y-axis indicates higher benefit, while lower utility on the x-axis indicates greater challenge. The current U.S. fuel cycle is plotted with a red symbol on the right of the figure, with benefit utility slightly greater than 0.5 and challenge utility of 1.0 (no challenge for development since this fuel cycle is already implemented). The two orange lines indicate thresholds of performance improvement that might be considered as providing substantial, or significant, improvement by decision makers. The figure shows 13 Evaluation Groups above the higher orange line, and four more Evaluation Groups above the lower orange line, showing varying levels of potential improvement and varying degrees of challenge in developing and deploying fuel cycles in these groups. Complete details for the other Scenarios, as well as the sensitivity analyses demonstrating the robustness of the identification of the promising fuel cycle options are provided in the E&S Study final report (Wigeland et al., 2014).

The most promising fuel cycles

Four groups of fuel cycles, described in Table 3, consistently provided the highest improvements compared to the current fuel cycle in the U.S., regardless of the perspective on the relative importance of the benefit criteria (Wigeland et al., 2014; Wigeland, 2015). The descriptions in Table 3 are only indicative of the fuel cycles included in each group, and the term “new natural uranium fuel” indicates that enrichment is not needed for either new uranium fuel resources or for the recycled uranium, in the equilibrium state.

Well-implemented fuel cycles in all of these groups were evaluated as being capable of providing substantial improvements compared to the current U.S. once-through fuel cycle using enriched uranium in light water reactors (LWRs) by reducing the amount

Fig. 2 Benefit versus challenge for the 40 Evaluation Groups for Scenario 1.

Table 3 Most Promising Fuel Cycle Groups.

<i>Evaluation Group</i>	<i>Most Promising Fuel Cycle Groups</i>
EG23	Continuous recycle of U/Pu with new natural-U fuel in fast critical reactors
EG24	Continuous recycle of U/TRU with new natural-U fuel in fast critical reactors
EG29	Continuous recycle of U/Pu with new natural-U fuel in both fast and thermal critical reactors
EG30	Continuous recycle of U/TRU with new natural-U fuel in both fast and thermal critical reactors

Note: U = uranium; Pu = plutonium; TRU = transuranic elements, i.e., atomic number higher than uranium (neptunium, plutonium, americium, curium, etc.); the term "U/Pu" indicates that uranium and Pu are recycled together, similarly the term "U/TRU" indicates that uranium and TRU are recycled together.

of waste generation and increasing the efficiency of using uranium fuel resources that would result if these fuel cycles were used, as follows (US Department of Energy, 1980):

- Greater than a factor of 10 reduction in the hazardous waste mass requiring geologic disposal
- Greater than a factor of 1000 reduction in uranium or thorium disposal
- Greater than a factor of 100 improvement in resource utilization

Part of the considerations in the E&S study that characterize implementing a fuel cycle "well" are developing and choosing technologies that allow safety requirements to be met, waste generation is minimized, safeguards and physical security can be implemented efficiently and effectively, and land and water resources are used efficiently (US Department of Energy, 1980). The fuel cycle characteristics that make these performance improvements possible are:

- Continuous recycle of actinides (U/Pu or U/TRU)
- Fast neutron-spectrum critical reactors with high internal conversion of fertile to fissile material
- Uranium-based fuel cycle with no uranium enrichment required once the fuel cycle is established

Table 4 summarizes the metric data from the E&S study for the Nuclear Waste Management and Resource Utilization metrics for the current U.S. fuel cycle (represented by EG01), and these four most promising fuel cycle groups, where metric data are given by a range of values rather than a single value to reflect the group nature of each fuel cycle group, and the metric data is intended to indicate the best performance potential by fuel cycles in each group. The E&S study results for the metric data show that these four groups of fuel cycles had the same performance improvement when compared to the current once-through U.S. fuel cycle using enriched uranium fuel in light-water reactors. The two metrics where EG29 has metric data in a different bin was caused by the much larger percentage of thermal reactors in the Analysis Example for this case (39% of total power generation) as compared to EG30 (13% of total power generation). It was recognized that if the ratio of thermal to fast reactors was the same in EG29 as it was in EG30, the metric data for EG29 would have been in the same bins as for EG30, prompting identification of EG29 as a most promising option (see footnotes for **Table 4**).

The E&S study also considered the challenge metrics, with the data for the most promising fuel cycle groups summarized in **Table 5** as additional background information for this study. For the metrics where the challenges were estimated as being the same for U/Pu and U/TRU recycle, all of these fuel cycles would face similar challenges, e.g., the time to develop the technologies is in the range of 10–25 years. However, in the E&S study, differences in challenge were noted for the development cost for U/Pu recycle which was estimated to be lower than that for U/TRU recycle, the deployment cost from prototypic validation

^aMetric data for the overall fuel cycle indicate the lowest value for any facility. These cases mainly show the difference between reprocessing and use of U/Pu as compared to U/TRU, where there is no experience with U/TRU regulation.

^bMarkets and market mechanisms are weak or exhibit distortions, requiring Federal government intervention in the form of direct investment or changes in law in order to establish and sustain market drivers. In addition, the fuel cycle option exhibits challenges with respect to the magnitude of capital required and payback prospects.

^cLikely to be “Similar” to the Current U.S. Fuel Cycle – The LCAE for the Evaluation Group is likely to be within about 30% of the LCAE for EG01. Placement in this bin requires the Analysis Example to have a mean LCAE that is no larger than 30% greater than EG01 and the uncertainty difference includes (or is close to including) the mean LCAE for EG01.

to first-of-a-kind (FOAK) commercial which was estimated to be lower for U/Pu recycle in fast reactors only, and the lack of any regulatory experience with facilities supporting U/TRU recycle.

These groups are the most promising options if the amount of reduction provided by these fuel cycles in the amount of waste generated and fuel resources needed is considered to be both important and substantial (since as noted above, choice of fuel cycle for most of the remaining criteria did not result in any improvement or differentiation), a judgment made by decision-makers and others.

None of these fuel cycles are ready to be deployed today. R&D must be conducted to develop the appropriate implementing technologies. The current state of knowledge and experience was examined to identify the R&D needs for each part of the fuel cycle. The R&D required to support these fuel cycles, along with some requirements for implementing technologies in order to achieve the benefits attributed to the fuel cycles, are as follows:

Reactor development

- R&D on fast critical reactors because these reactors facilitate effective consumption of actinide elements and efficient use of uranium fuel resources (which may also include intermediate spectrum reactors since these were grouped with fast reactors in the Study; fast subcritical reactors are also in this Evaluation Group with similar physics-based performance but face greater challenges than critical reactors, including for LCAE, so the supporting R&D is not listed)
 - The reactors must have conversion of fertile materials to more fissionable materials sufficient to sustain operation without the need for ongoing supplies of enriched uranium

Separations/reprocessing development

- R&D on separation of U/Pu or U/TRU from irradiated fuel to make them available for recycle
 - The separations processes should have total nominal product losses of about 1% or less to waste disposal; smaller losses may not be of further benefit

Fuel development

- R&D on recycle fuel development to facilitate use of recovered U/Pu or U/TRU as fuel
 - The fuel should have irradiation capability comparable to or greater than today’s fuel

In addition, for any fuel cycle, an R&D goal should be to reduce waste generation throughout the fuel cycle, including developing waste forms that reduce the volume of any HLW since HLW volume can be an important factor for deep geologic disposal.

Minor actinide recycle

Both U/Pu and U/TRU recycle fuel cycles could each provide benefits with respect to the other depending on where the minor actinides were in the fuel cycle. For U/Pu recycle fuel cycles, whether only fast reactors are used (EG23) or if fast reactors provide the fissile materials to operate thermal reactors (EG29), the minor actinides are intentionally part of the HLW and would only potentially be present in the rest of the fuel cycle as a contaminant from reprocessing activities. Implementing a fuel cycle that recycles U/Pu allows the use of fuels with a significant experience base, and these fuels could be fabricated and handled with less shielding than is needed when the

minor actinides are in the fuel as is the case with U/TRU recycle. The irradiated U/Pu fuel also has lower decay heat than when U/TRU is recycled, allowing handling and shipping sooner with fewer shipments to processing facilities. Reprocessing technologies for recovering U/Pu are available that are similar to those that have been deployed industrially, potentially reducing R&D needs. However, at the same time, even though the presence of the minor actinides in the HLW is accommodated by existing waste form technologies, the minor actinides could complicate advanced waste form development and affect the durability of an advanced waste form due to the higher α radiation, potentially increasing R&D needs in this area. In addition, the HLW minor actinide content, especially Am241, adds decay heat that needs to be managed during handling and storage, and which may increase the size of a geologic repository due to the potential for requiring an increased area for disposal of HLW with higher decay heat.

In contrast, recycle of the minor actinides in U/TRU recycle fuel cycles, whether only fast reactors are used (EG24) or if fast reactors provide the fissile materials to operate thermal reactors (EG30), keeps the minor actinides out of the HLW except for processing losses. This would allow the use of existing waste form technologies and has the potential to simplify advanced waste form development. The lower HLW decay heat may enable more compact disposal, reducing the size requirements for a geologic repository. However, these benefits also come with the development challenges associated with keeping the minor actinides within the fuel cycle. As mentioned above, U/TRU recycle fuels will require more shielding for handling and fuel fabrication, there is little to no experience with such U/TRU recycle fuels in a reactor, and the handling and storage of the irradiated fuel must deal with the higher decay heat. Reprocessing technology needs to be developed, and R&D has been ongoing to achieve U/TRU recovery.

It is also possible to consider recycle of just one or more of the minor actinides rather than all of them together. For example, if americium is recycled along with the U/Pu, the decay heat from the americium is kept out of the HLW, potentially benefitting the space required for waste disposal, but there may still be complications for advanced waste form development due to α damage, mainly from curium. At the same time, the presence of americium in the recycle fuel increases the decay heat, affecting storage and handling, and there is little to no experience with such fuels although challenges related to the recycle of americium have been identified in other studies. This example illustrates that such partial recycle of the minor actinides may move specific benefits and challenges between the different parts of the fuel cycle but they will always be present.

Either U/Pu and U/TRU recycle fuel cycles has both benefits and challenges. It appears that the benefits are associated with the parts of the fuel cycle that do not contain significant amounts of minor actinides, and the R&D challenges are associated with the parts of the fuel cycle where the minor actinides are present.

Additional potentially promising fuel cycles

Recognizing that organizing the promising Evaluation Groups into sets of similar potential benefit is somewhat arbitrary, the thresholds on Fig. 2 (Scenario 1, equal criteria tradeoff factors) and sensitivity analyses were used as guides to identify 11 additional *potentially promising groups of fuel cycles* that provide somewhat lower, but still potentially substantial, beneficial improvements than the four discussed above. While it is again a matter of judgment by decision-makers and others whether the improvements offered by these groups are considered both important and substantial, each of these groups perform better than the current U.S. fuel cycle when almost any, but not all, combinations of criteria are considered. (Evaluation Groups are listed in numerical order, with a short description indicative of the fuel cycles included in each Evaluation Group):

- EG06—Once-through using Th fuel to very high burnup in thermal EDS
- EG07—Once-through using natural-U fuel to very high burnup in thermal or fast EDS
- EG08—Once-through using Th fuel to very high burnup in fast EDS
- EG09—Limited recycle of U/TRU with new natural-U fuel to very high burnup in fast critical reactors
- EG26—Continuous recycle of $^{233}\text{U}/\text{Th}$ with new Th fuel in thermal critical reactors
- EG28—Continuous recycle of $^{233}\text{U}/\text{Th}$ with new Th fuel in fast critical reactors
- EG33—Continuous recycle of U/Pu with new natural-U fuel in both fast EDS and thermal critical reactors
- EG34—Continuous recycle of U/TRU with new natural-U fuel in both fast EDS and thermal critical reactors
- EG37—Continuous recycle of $^{233}\text{U}/\text{Th}$ with new enriched U/Th fuel in both fast and thermal critical reactors
- EG38—Continuous recycle of $^{233}\text{U}/\text{Th}$ with new Th fuel in both fast and thermal critical reactors
- EG40—Continuous recycle of $^{233}\text{U}/\text{Th}$ with new Th fuel in fast EDS and thermal critical reactors

While the R&D listed for the four most promising options would also support some of these fuel cycles, other, different or additional, R&D is needed to support development of some of these additional potentially promising options, as follows:

Reactor development

- R&D on thermal critical neutron reactors because these reactors facilitate efficient conversion of thorium to usable fuel
 - The reactors must have conversion of fertile thorium materials to more fissionable materials sufficient to sustain operation without the need for ongoing supplies of fissile materials such as enriched uranium
- R&D on externally-driven systems (EDS) because subcritical reactors can provide an external source of neutrons to facilitate conversion of fertile materials to more fissionable materials (although the greater challenges for such systems, including LCAE, should be recognized)

- The reactors must have conversion of fertile thorium and/or uranium materials to more fissionable materials sufficient to support operation without the need for ongoing supplies of fissile materials such as enriched uranium
- The additional safety challenges identified for EDS compared to critical reactors should be addressed

Separations/reprocessing development

- R&D on separation of $^{233}\text{U}/\text{Th}$ from irradiated fuel to make it available for recycle
 - The separations processes should have total nominal product losses of 1% or less to waste disposal; larger losses may be acceptable while still preserving sufficient benefits, but smaller losses may not be of further benefit

Fuel development

- R&D on recycle fuel development to facilitate use of separated $^{233}\text{U}/\text{Th}$ as fuel
 - The fuel should have irradiation capability comparable to or greater than today's fuel
- R&D on very high burnup fuel to facilitate greater resource utilization
 - The fuel should have irradiation capability several times higher than today's fuel and even well beyond experimentally-demonstrated capability for advanced fuel

Other potentially promising fuel cycles

In addition to the Evaluation Groups listed above, using the lower threshold in [Fig. 2](#) and the sensitivity analyses described in Appendix F of [Wigeland et al. \(2014\)](#), a few additional lesser performing fuel cycles were identified that may be potentially promising depending on the relative importance of the criteria and the underlying metrics, again if the improvements are considered both important and substantial by decision-makers and others (Evaluation Groups are listed in numerical order, with a short description indicative of the fuel cycles included in each Evaluation Group):

- EG04—Once-through using natural-U fuel to very high burnup in fast critical reactors
- EG10—Limited recycle of $^{233}\text{U}/\text{Th}$ with new Th fuel in fast and/or thermal critical reactors
- EG14—Limited recycle of U/Pu with new natural-U fuel in both fast and thermal critical reactors

The R&D requirements already listed above are sufficient to support development of these fuel cycles.

Insights about fuel cycles

Based on the promising fuel cycles identified by the evaluation and screening process, certain fuel cycle characteristics were identified that provide beneficial performance improvements with respect to the Evaluation Metrics, criteria and scenarios:

- Continuous recycle of actinide elements—the actinide elements (thorium, protactinium, uranium, plutonium, neptunium, americium, curium, and so on) are major contributors to the long-lived hazard from irradiation of nuclear fuel, and can be a source of energy, some directly as fuel and others by conversion to usable fuel. Recycling the actinide elements benefits two of the Evaluation Criteria: efficient use of fuel resources and reduction of nuclear waste generation.
- Fast neutron irradiation—fast neutron fission has a much more favorable fission-to-capture ratio for neutrons for certain isotopes, greatly increasing fissioning of isotopes such as ^{240}Pu and enhancing fissioning of ^{239}Pu , reducing the buildup of long-lived highly radioactive higher actinide isotopes.
- Critical reactors—use of reactors that are capable of sustaining fission without the need for an external source of neutrons lowers development risk, lowers safety challenges, and lowers overall costs as compared to externally-driven systems.
- High-internal conversion—efficient conversion of fertile fuel materials to more easily fissionable isotopes allows efficient use of fuel without the need for uranium enrichment for continued operation, increasing resource utilization and reducing waste generation. Fast neutron fission also produces more neutrons per fission than thermal fission, facilitating the high-internal conversion needed for self-sustaining fuel cycles.
- Nuclear fuels—irradiating uranium-based fuels in the fast spectrum provides higher internal conversion capability than thorium-based fuels in either a thermal or fast spectrum, facilitating effective resource utilization as long as uranium enrichment is not required for continued operation, as evidenced by the four most promising options identified in the Study. However, even though uranium may be more readily used to achieve greater resource utilization, potentially promising options were also identified for fuel cycle options using thorium-based, and uranium/thorium-based fuels, as listed above.
- Safety—promising fuel cycles are capable of safe deployment, with many having safety challenges comparable to the current U.S. fuel cycle. Enhanced safety is not provided by choice of fuel cycle, but may be provided by the choice of implementing technologies and facility design

In addition to these specific fuel cycle characteristics, other more general concepts applicable to many or all fuel cycles were examined for potential benefit:

- Extended decay storage (SNF and/or UNF, (*Note:* SNF denotes spent nuclear fuel, which is irradiated fuel destined for disposal. UNF, used nuclear fuel, is used to denote irradiated fuel that is going to be reprocessed.) products, or wastes) can:
 - slowly lower radiation level by radioactive decay to potentially reduce worker exposure or shielding requirements, but the remaining radiation is sufficient to still require remote handling of the materials
 - favorably affect recycle of some actinide elements such as curium, but may adversely affect recycle of other actinide elements such as plutonium
 - slowly lower decay heat at the time of disposal for SNF, facilitating handling and emplacement, but is most effective for the HLW from recycle fuel cycles where most of the content is fission products with a relatively short radioactive half-life.
- Processing of spent fuel prior to disposal, not for recycle (for once-through or limited recycle fuel cycles only) to separate the uranium or thorium from the fission products and any long-lived highly-radioactive elements may also greatly reduce the amount of materials requiring isolation such as that provided by deep geologic disposal. However, the uranium and/or thorium separated and recovered during processing still need to be disposed as waste, in contrast to recycle fuel cycles where such materials can be reused to reduce overall waste generation from the fuel cycle and increase utilization of fuel resources.
 - If the separated uranium or thorium can be disposed with much lower isolation requirements, then processing of SNF prior to disposal can reduce the amount of waste requiring geologic isolation, e.g., HLW, by a factor of 10 or more.
 - If the disposal requirements for the recovered uranium and/or thorium are comparable to those for SNF or HLW, then there would appear to be no benefit from processing SNF prior to disposal.
- Minor actinide separation and transmutation
 - While minor actinide separation and recycle in addition to uranium/plutonium recycle (i.e., TRU recycle) may further reduce waste generation and increase resource utilization as compared to uranium/plutonium recycle, no improvement was noted for the metrics used in this Study for the most promising options of continuous recycle in fast reactors. Additionally, at the fuel cycle level, it was noted that there would be no difference in potential benefit for TRU recycle whether all of the minor actinide elements are recycled individually in different fuels, as a single group in one fuel, or in combination with fuel containing plutonium. Thorium-based fuel cycles have little minor actinide content in the irradiated fuel and therefore would not have substantial benefits from minor actinide separation and transmutation.

Challenges for fuel cycle development and deployment

The criteria indicating the challenges associated with developing and deploying an alternative fuel cycle identified several commonalities among essentially all of the promising fuel cycle options:

- Two of the most promising fuel cycles have estimated total development costs in the range of \$2 - \$10 billion (EG23, EG29), while the other two (EG24, EG30) are in the range of \$10–\$25 billion, as are most of the other promising fuel cycles, and estimated development times in the range of 10–25 years to bring all enabling implementing technologies and facilities to successful demonstration at engineering scale. The government has historically been the major source of funding for such R&D activities.
- Following completion of the technology development, the promising options have an estimated initial total deployment cost in the range of either \$10–\$25 billion (EG06, EG07, EG08, EG23) or \$25–\$50 billion (the remaining promising options) to continue development from engineering demonstration through the deployment of first-of-a-kind commercial facilities. Cost-sharing between industry and government may be expected for such development. Fully deploying an alternative fuel cycle to replace the current U.S. fuel cycle would likely require several hundred billion dollars or more, comparable to the cost of continuing with the current fuel cycle replacing existing reactors as they are retired with new similar reactors.
- The market disincentives and barriers to commercial implementation of nearly all of the promising options are expected to be very significant, such that in the U.S., Federal government intervention in the form of direct investment, mandates, or changes in law in order to establish and sustain market drivers will likely be required for full-scale implementation of a new fuel cycle. An example of this is the current SNF disposal fee based on energy production that provides a disincentive for waste reduction because for a given amount of energy production, the disposal fee is the same regardless of waste amount.

Based on the Study results for the estimated levelized cost of electricity at equilibrium (LCAE), many of the promising options may be expected to have electricity production costs that are similar to, or close to, the estimated LCAE for the current U.S. fuel cycle as shown in [Fig. 3](#) where the difference is given in mills per kilowatt-hour ([Wigeland et al., 2014](#)). Further information on the economics of nuclear energy is provided in Chapter 00222 of this encyclopedia ([Rothwell, 2021](#)).

The four most promising options, EG23, EG24, EG29, and EG30, all have a mean estimated LCAE within 5 mills per kilowatt-hour of the cost of continuing with the current U.S. fuel cycle, which has an LCAE of about 50 mills per kilowatt-hour. It was observed that more complex fuel cycles could cost more to build and operate, but could have offsetting lower costs elsewhere in the fuel cycle, and the dominant fuel cycle cost contributor is for the reactors. For example, a recycle fuel cycle adds costs for reprocessing and recycling, but may have lower fuel resource costs and may eliminate enrichment costs.

Fig. 3 Difference in LCAE in mils per kilowatt-hour for the analysis example of each Evaluation Group and the analysis example of EG01, ordered by increasing positive difference.

Since the LCAE was not grouped with the other challenge criteria but provided the information separately as additional information, it is instructive to examine the differences in LCAE for the best performing Evaluation Groups. Fig. 4 shows the main cost contributions to the estimated mean LCAE for Analysis Examples EG23, EG24, EG29 and EG30 and compared directly to the cost

Fig. 4 Comparison of the levelized cost of electricity at equilibrium cost breakdown for EG01, EG23, EG24, EG29 and EG30 using averages of the calculated values.

contributions of EG01. The Analysis Examples EG23 and EG24 are fast reactors operating on a closed U/Pu and U/TRU cycle, respectively, which are self-sufficient due to Pu and TRU production. The Analysis Examples EG29 and EG30 are, respectively, net Pu and TRU producing fast reactors that breed sufficient excess fissile to supply thermal reactors so that uranium enrichment is not needed. While the O&M costs are about the same for all five systems, the charges for capital cost recovery are, as expected, higher for EG23 and EG24 which use only fast reactors. Evaluation Groups EG29 and EG30, which involve a combination of fast and thermal reactors, have capital cost recovery charges that are proportional to the fraction of each reactor type utilized in the system.

Glossary

Ac Actinides, elements with atomic numbers 89 to 103.

Actinides Eigen-composition Stabilized actinides composition, an equilibrium composition which results from a long irradiation of one parent nuclide or their mixture. Necessary condition for the stabilization is that the mass of parent nuclide/s and the irradiation flux do not vary strongly. It is specific and inherent feature for every reactor and every parent nuclide/s and it represents the Eigen-vector of the respective Bateman equation.

B&B Breed-and-Burn; a mode of open cycle operation, where the fissile excess bred during irradiation is equal or higher than the discharged fissile mass after the irradiation. The reactor burns its own bred fuel. The discharged fuel does not need to be recycled and the fresh fuel does not need to contain primordial or synthetic fissile nuclides.

Binding energy per nucleon Energy normalized per nucleon, which would be released when nuclei would be synthesized from protons and neutrons or which would be needed to disassemble the nucleus into protons and neutrons.

Breeding Transmutation of actinide nuclide initiated by neutron capture, which increases fission probability. Typically, primordial non-fissile (fertile) nuclides ^{232}Th and ^{238}U are transmuted into synthetic (man-made) fissile ^{233}U and ^{239}Pu .

Burnup Share of already fissioned actinides. It can be expressed in FIMA % (Fissions per Initial Metal Atom) or as energy released from given mass of actinides in MWd/kg (Megawatt days per kilogram). Since the energy per fission is approximately the same for all actinide nuclides, values expressed in these two units are proportional and roughly 10 times higher for the second unit.

Closed cycle A chain of process steps which is closed for the respective working medium. The medium, in nuclear fuel cycle the actinides, is recycled and does not extensively leave the chain.

Cross-section A measure of the probability that neutron will interact when flying by with the respective nucleus (microscopic cross-section) or when fling through with the respective nuclei concentration (macroscopic cross-section).

Decay series Series of consecutive radioactive decays and intermediate decay products, which are needed to reach the final stable nuclide. All actinides are radioactive and decay through one of the four existing actinides alpha decay series.

Fertile nuclide Nuclide which can be transmuted into fissile nuclide.

Fission barrier It represents the minimal added energy by the interacting particle to cause nuclear fission.

FPs Fission Products, typically two fragments of actinides fission.

Irradiation chain Series of consecutive transmutations and of the respective daughter products induced by neutron irradiation of one parent nuclide, e.g., ^{232}Th or ^{238}U . The radioactive decays of the daughter products are part of the chain.

MCFR Molten Chloride Fast Reactor, unmoderated MSR type based on molten chlorides.

MSR Molten Salt Reactor, a reactor in which the molten salt has substantial function, in this chapter the label is used for graphite moderated fluoride salt based MSR.

Neutron economy Balance between neutron generation and neutron losses in a reactor. Good neutron economy has high neutron generation and small neutron losses by parasitic absorption and leakage from the reactor.

Open cycle A chain of process steps which is open for the respective working medium. The medium, in nuclear fuel cycle the actinides, is not recycled and leaves extensively the chain.

Primordial actinides Actinide nuclides, presumably originated by rapid neutron capture process during a supernova explosion, which have long enough half-life for radioactive decay to be still present on the earth.

Self-sustaining breeding Breeding process where breeding rate $\geq$ fission rate, the mass of fissile synthetic nuclides is conserved in the reactor, and fission chain reaction is sustained solely by these synthetic nuclides. A long time-horizon is being considered in this article.

Synthetic actinides Actinide nuclides originated, typically by neutron-induced transmutation, from primordial actinides. Synthetic nuclides are, by definition, a much broader group than minor actinides or trans-uranic elements. For thorium and uranium elements, both primordial and synthetic isotopes exist.

Waste Waste is an unwanted side product, which is further unusable. In the nuclear fuel cycle, synthetic actinides represent a side product, which is reusable. However, they can be declared as a waste by nuclear fuel cycle policy or when it is too laborious to recover them, e.g., from reprocessing losses of certain fuel forms.

Introduction

This is the first of a series of three chapters that is dedicated to the identification of the advanced reactor technologies that are capable of self-sustaining breeding when fueled with either ^{232}Th or ^{238}U , and to the investigation of equilibrium fuel cycles properties and neutronics performance. This first chapter characterizes the available fuel resources from the nuclear and reactor physics perspective. It presents in detail the features of the ^{232}Th and ^{238}U irradiation chains using two advanced reactors adopted from (Losa, 2016; Krepel and Losa, 2019) as an example and the knowledge of equilibrium nuclides concentration and reaction rates is used for characterization of neutron economy and ingestion radiotoxicity related to these chains. The second chapter (Krepel and Losa, 2021) determines the equilibrium fuel composition in advanced reactors and compares the basic features of the equilibrium fuel cycle and selected reactor neutronic performance characteristics at the equilibrium state. The third chapter (Krepel, 2021) evaluates the fuel cycle performance from a neutronics perspective by means of the earlier obtained equilibrium parameters. It provides an additional insight on why some advanced reactor concepts can act as self-sustaining breeders in closed or even open fuel cycle, while others do not.

Actinides as a resource

In terms of producing energy by atomic nuclei transmutation, the nuclear fission chain reaction is the only alternative to nuclear fusion. From the resources available on earth only actinides can be utilized in nuclear fission reactors. They were presumably originated by rapid neutron capture processes in the core of a collapsing star and expelled into space by gravitational shock waves during its supernova explosion. Hence, the nuclear fuel cycle relies on a resource, which is not renewable. Three dominating primordial actinide nuclides are present on earth: ^{235}U , ^{238}U and ^{232}Th . Their estimated reserves somewhat follow their half-lives for radioactive decay (see Fig. 1). Accordingly, there is probably three to four times more thorium than uranium, and the ^{235}U share in natural uranium is limited to 0.7%. The ^{235}U reserves are the smallest; at the same time, it is the only primordial nuclide fissile by thermal neutrons. Therefore, it can be directly utilized in nuclear fission reactors. The other two primordial nuclides can also be utilized, albeit not directly and not in all reactors. Accordingly, they are foreseen as a resource for advanced reactors (Stanculescu, 2021).

Primordial and synthetic actinides

Actinides nuclides can be divided into primordial and synthetic. The three major primordial nuclides have half-lives of the same order of magnitude as the age of earth (see Fig. 1). The synthetic actinides are originated by primordial nuclides transmutation, typically by neutron capture reactions. Fission reactions also represents nuclear transmutation; however, the resulting Fission Products (FPs) do not belong to the chemical group of actinides.

Fission and transmutation

The ^{235}U reserves are the smallest; at the same time, ^{235}U is the only primordial nuclide suitable for establishing a fission chain reaction. Consequently, vast majority of current nuclear power plants rely on enriched uranium and fission predominantly ^{235}U .

Fig. 1 Half-life and type (alpha or beta) of radioactive decay for primordial and synthetic actinides.

The consumption of natural uranium in these reactors does not exceed 1%. If also the thorium reserves are considered, not more than 0.2% of primordial actinides are utilized for energy production in ^{235}U -fueled reactors. Moreover, the discharged fuel from these reactors contains synthetic actinide nuclides, e.g., ^{234}U , ^{236}U , ^{237}Np , ^{239}Pu , ^{240}Pu , ^{241}Am , originated from ^{235}U and ^{238}U irradiation. Synthetic actinides are the major cause of the long-term stewardship burden related to the final spent fuel repository. Their recycling in ^{235}U -fueled reactors is possible, but only to a limited extent. Since the fuel is usually not recycled, these reactors are operated in so-called open cycle (Crawford, 2021).

Already in 1940 it was discovered that transmutation of fertile ^{238}U results in fissile ^{239}Pu (Seaborg, 1994). Equally, fertile ^{232}Th can be transmuted into fissile ^{233}U . This transmutation process is called breeding and reactors relying on this process are called breeders. Once originated, the synthetic nuclides ^{239}Pu and ^{233}U can sustain the fission chain reaction and the breeding process itself. Accordingly, they practically act as a catalyzer for energy production from the primordial nuclides ^{238}U and ^{232}Th . Even though the first ^{239}Pu was generated by a different (particle accelerator based) nuclear process, the fission chain reaction driven by ^{235}U is the most natural option to generate the initial synthetic nuclides and to launch the self-sustaining breeding. However, not all advanced reactors can sustain this process, and some perform better than others. The aim of this article is to provide insight from a nuclear and reactor physics perspective, as to why it is so.

Natural resources utilization

The amount of primordial actinides on earth is finite and not renewable. Accordingly, the sustainability of the nuclear fuel cycle is determined by its capability to maximize its natural resources utilization. As already mentioned, utilization of natural uranium does not exceed 1% in ^{235}U -based open cycle and it can reach up to 20–35% in the breed-and-burn (B&B) open cycle mode (Qvist, 2021; Krepel and Kramer, 2021; Greenspan, 2021). Nonetheless, the highest resources utilization can be achieved by breeding in a closed cycle (Wigeland, 2021; Krepel et al., 2018). The cycle is called closed, because actinides as the working medium are recycled and do not significantly leave the cycle. Achievable utilization in this fuel cycle is limited solely by the recycling losses (losses in fuel reprocessing and refabrication) and fuel burnup per cycle (see Fig. 2). It can reach up to 95–98% of the resources. Discharged fuel burnup influences the losses, because fuel with higher burnup is less often recycled. In an ideal reactor, the discharged fuel burnup should be 100% FIMA and reprocessing frequency zero. Should this be possible, breeding in closed cycle and in the B&B open cycle will become identical. Even though unrealistic, it may be approached in reactors with liquid fuel from which solely FPs are extracted from the core.

The reason why not all reactor concepts are capable of being self-sustaining (isobreeding/break-even) breeders is the tight neutron economy. Simple fuel balance of a breeder reactor requires that for each fissioned synthetic nucleus at least one transmutation of primordial nuclide takes place. Accordingly, up to two neutrons are needed from each fission: one for sustaining the chain reaction and one for maintaining of the fissile material balance. The neutron economy of a breeder is thus very tight. Less than one neutron per fission should be lost due to the neutron leakage or parasitic neutron capture in the coolant and structural materials or in the fuel itself. Furthermore, once discharged from a breeder, the irradiated fuel must be recycled to maintain the fissile material balance. The only exception from this requirement are very strong breeders, where the fissile excess bred during the irradiation would be equal or higher than the discharged fissile mass after the irradiation. Since the bred excess is not necessary for the fissile

Fig. 2 Natural resources utilization as a function of reprocessing frequency (inversely proportional to fuel burnup per cycle) and losses in recycling. From Krepel J, Hombourger B and Losa E (2018) Fuel cycle sustainability of Molten Salt Reactor concepts in comparison with other selected reactors. *PHYTRA4, Marrakech, Morocco, September 17-19*.

mass conservation, these very strong breeders can self-sustain the breeding in open cycle in the B&B mode (Qvist, 2021). The name is derived from the fact that the loaded fuel does not need to contain fissile actinides; they are bred during the irradiation in the B&B reactor and suitable fraction of them fission in that reactor.

Catalyzer and waste, simultaneously

Synthetic actinide nuclides are the necessary catalyzer for the primordial actinides utilization. However, in the open fuel cycle practiced today, or as losses of recycling in a closed cycle, they cause a long-term stewardship burden. Their half-lives are too short to be primordial, but too long to disappear swiftly once originated (see Fig. 1). Furthermore, synthetic actinides decay in chains and one fast decaying nuclide can be a source of another slow decaying nuclide and vice-versa. The social and environmental sustainability considerations require minimal long-term stewardship burden; hence, the amount of synthetic actinides in the waste stream should be minimized. The burden should be measured in terms of their long-term radiotoxicity per unit of produced energy. Indefinite recycling in closed cycle provides the ultimate solution not only for maximizing resources utilization, but also for minimizing waste production. The recycling losses define the achievable limit for both measures. In the open cycle, all discharged actinides are considered as a waste and the policy of many countries is to seal them forever in a spent fuel repository without recycling. However, synthetic actinides are in reality a resource and they are treated as such in this article.

Irradiation chains of primordial actinides

Since any synthetic actinide, as a transmutation product, can undergo another transmutation, the irradiation of primordial actinides by neutrons results in a chain of synthetic actinides. The irradiation chains of ^{232}Th and ^{238}U are especially relevant for natural resources utilization.

Irradiation chains

For each reactor and for each primordial nuclide, the composition of generated synthetic actinides tends to stabilize and reaches equilibrium concentration after sufficiently long neutron irradiation. Necessary condition for the composition to converge to its equilibrium state is that the mass of irradiated nuclide and the neutron flux do not vary strongly. Hence, when the same fuel is repetitively irradiated in closed cycle, soon or later the equilibrium composition of synthetic actinides will be established. This stabilized actinides composition is actually the Eigen-composition of the respective Bateman equation (Bateman, 1910) and it is specific and inherent feature of given reactor and parent primordial nuclide. For the illustrative purposes, the ^{232}Th and ^{238}U irradiation chains in thermal and fast neutron spectra are presented in Figs. 3–6. The respective reactors used for the simulation are graphite moderated Molten Salt Reactor (MSR) with fuel in form of eutectic mixture of lithium fluoride and actinides tetra-fluoride salts and Molten Chloride Fast Reactor (MCFR) with fuel in form of eutectic mixture of sodium chloride and actinides tetra-chloride salts. For more detail about the selected reactors and modeling assumptions refer to (Krepel and Losa, 2021).

Even in an open cycle, the fuel composition tends to converge to equilibrium. The ^{238}U mass does not vary strongly in the ^{235}U -fueled reactors. Already at the end of an open-cycle irradiation, the immediate daughter product ^{239}Pu is practically at equilibrium concentration and its daughter ^{240}Pu close to it. The concentrations of higher plutonium isotopes are not yet converged, and

Fig. 6 Example of the ^{238}U irradiation chain with relative masses and reaction rates in MCFR. From Losa E (2016) *U-Pu and Th-U Fuel Cycle Closure*, PhD thesis. Prague: Czech Technical University in Prague, Department of Nuclear Reactors.

americium, curium, and their daughters will need substantially longer time for stabilization. The convergence process of higher plutonium isotopes is also the reason why plutonium is recycled optionally only once in ^{235}U -fueled reactors (although a second and third plutonium recycling is being considered in France (Guillaume et al., 2018)). The plutonium multi-recycling in ^{235}U -fueled reactors will not substantially increase the resources utilization; at the same time, it surely helps to minimize the synthetic actinides amount in the waste stream.

During the irradiation of ^{235}U , concentrations of daughter products like ^{234}U , ^{236}U and ^{237}Np also tends to equalize quite fast. Nonetheless, ^{235}U is fissile and its own concentration strongly decreases during the irradiation. Hence, equilibrium as such is never reached. Even though it is not accurate, the basic features of the ^{235}U irradiation chain can be understood from the ^{232}Th chain, because it is its sub-set. Based on the example in Fig. 3, for instance, the equilibrium concentration of ^{236}U seems to be higher than the ^{235}U concentration in a thermal spectrum reactor. However, also in fast neutron spectrum (see Fig. 5) the ^{236}U concentration is similar to ^{235}U concentration. The irradiated uranium, with left-over ^{235}U and its daughter products ^{234}U and ^{236}U can be also recycled in ^{235}U -fueled reactors. In this case it needs to pass again through the enrichment process to reduce the ^{238}U amount.

Nuclear physics implications

There is some obvious symmetry in the irradiation chains presented in Figs. 3 and 4 or in Figs. 5 and 6. This symmetry, but also all other features of nuclides such as: type of radioactive decay, half-lives, absorption cross-section, fission-to-capture probability, or even the energy released per fission can be explained by nuclear physics and, in particular, by the respective binding energy per nucleon and by the fission barrier.

Binding energy and line of stability

The binding energy per nucleon (protons and neutrons in the nucleus) is well described by empirical liquid drop model or actually the Weizsäcker formula (Weizsäcker, 1935). This formula has five terms: volume, surface, Coulomb, asymmetry and pairing. Balance of these terms define a line of stability. At this line or close to it the binding energy per nucleon is the highest and the nuclei are most stable. The line is defined by an interplay of only three terms of the Weizsäcker formula, because the volume term has no impact on the stability and the pairing term causes only local perturbations. The surface term is important for light nuclei and plays a role in fusion reactions but is less relevant for heavy nuclei and their fission. Furthermore, for nuclei, with the same number of nucleons, which are located on a diagonal (roughly orthogonal to the stability line in Fig. 7), the surface term is the same. The highest binding energy on this diagonal is determined by the balance of the Coulomb and asymmetry terms. These two terms quantify the reduction of binding energy caused by proton repulsive forces and by asymmetry between total proton and neutron count, see also Napolitano (2021) and Klay (2021).

Repetitiveness of nuclei properties

The Coulomb repulsive forces in actinide nuclei, with more than 89 protons, are enormous. The higher neutron count reduces the proton repulsive force. At the same time, it weakens the binding energy through the asymmetry term. Maximal stability of actinide nuclei is reached at 1.55–1.6 neutrons per proton. Yet they are all unstable and undergo radioactive decay. The approximate line of stability shown in Fig. 7 follows a trend where the same stability is obtained when addition of one proton is accompanied by addition of two neutrons. Nonetheless, with increasing proton number, the stability of actinides generally decreases. Moreover, due to the pairing effect, nuclei with even number of neutrons and/or protons have higher binding energy. Accordingly, properties of the nuclei along the stability line are repeating with steps of 2 protons and 4 neutrons ($+2p, +4n$). This repetition, illustrated in Table 1, is the major reason why exactly ^{232}Th and ^{238}U are present on earth and why there is a symmetry of their irradiation chains. Based on this repetition, ^{244}Pu could have been the third primordial actinide nuclide. Unfortunately, its half-life for radioactive decay is 56 times shorter than for ^{238}U . Nonetheless, for illustration of the repetitiveness, it is included in Table 1.

Nuclides in the ^{232}Th irradiation chain have less protons and are generally more stable. The respective longer half-lives are the reason why the estimated ^{232}Th reserves are higher and why the initial radiotoxicity of the respective synthetic actinides seems lower (refer to the later discussion). Nonetheless, the longer half-lives also result in a 11 times higher ^{233}Pa concentration than the respective ^{239}Np concentration in the ^{238}U chain and increase so the parasitic neutron capture probability. The second major difference between the ^{232}Th and ^{238}U irradiation chains is the very short half-life of ^{241}Pu and its different type of decay. At the corresponding position in the ^{232}Th chain, there is α decaying ^{235}U with the third longest half-life. As illustrated in Fig. 7, the major irradiation chain can branch at the ^{241}Pu position. Dominant direction after this split depends on the ratio of decay and capture rates. In a thermal neutron spectrum, in which the ^{241}Pu capture cross-section is larger and its resulting concentration is thus smaller, the capture rate dominates over the decay rate (see Figs. 3 and 4). In a fast neutron spectrum it can be the opposite (see Figs. 5 and 6).

Fission probability and cross-section amplitude

The fission barrier, as the second nuclear physics parameter, is not presented here graphically, but in the area of interest it has slight slope (Petermann et al., 2012); it decreases with increasing number of protons and decreasing number of neutron in the nucleus.

Fig. 7 Local nuclide chart of the actinides area with highlighted approximated line of stability and major paths for the ^{232}Th and ^{238}U irradiation chains with highlighted major fissile nuclides.

The Coulombian repulsive forces get stronger and the fission barrier weaker, when more protons are closer to each other (less neutrons). This is partly the reason why ^{233}U (see Fig. 7) has higher fission-to-capture probability than ^{235}U or ^{239}Pu . At the same time, ^{233}U and ^{235}U as the major fissile nuclides in ^{232}Th chain have lower number of nucleons than the respective ^{239}Pu in ^{238}U chain and release so, in average, less neutrons per fission.

To fission, each nucleus needs to overcome the fission barrier. The required energy is provided by the interacting neutron in potential (its binding energy) and kinetic form (its collision speed). Practically all actinide nuclides can be fissioned by fast neutrons with a certain probability. From this perspective, ^{238}U can be fissioned at lower neutron speed than ^{232}Th (see the respective fission rates in Table 3), what represents certain advantage for the ^{238}U irradiation chain. Possibility of fission by thermal neutrons is determined solely by the balance between fission barrier and binding energy. Since the binding energy depends also on the pairing effect, nuclei with odd number of neutrons are usually fissile by thermal neutrons.

The pairing effect is also relevant for the absolute size of neutron absorption cross-section. Nuclei with even number of neutrons have typically lower cross-sections for interaction with neutrons. This is actually the reason why the concentration of fissile nuclide in self-sustaining breeders is one or two orders of magnitude lower than the concentration of fertile nuclide.

Neutron economy

In the equilibrium irradiation chain, see Figs. 3–6, the actinides concentrations and reaction rates are stabilized. As a result, the equilibrium chain provides many perspectives and options allowing for estimating its neutron economy. The basic question is whether the reactor core could be critical with such an equilibrium fuel composition. Since all reaction rates in the presented chains are normalized to the fission rate and shown in percent, they can be interpreted as the history of one neutron generation, which was born from 100 fissions.

Table 1 Illustration of actinides properties repetitiveness along the line of stability with the steps of 2 protons and 4 neutrons for ^{232}Th , ^{238}U and ^{244}Pu irradiation chains.

Nuclide chains			Position	Protons (p)	Neutrons (n)	Fissile ^a	Decay	Longest half-life	Half-life ratio 1:2	Half-life ratio 2:3	Comment

^aSimplified statement about fission probability by thermal neutrons.

^bIn these cases, the pairing term shifts the balance between Coulomb and asymmetry terms to the right from the stability line. ^{232}Th , ^{238}U and ^{244}Pu belong to the top four actinides with longest half-lives (see Fig. 1).

^cThese nuclides are close to the stability line. However, their behavior is irregular. ^{235}U and ^{247}Cm , as the third and sixth most stable actinide nuclides decay through α decay. Nevertheless, ^{241}Pu decays through β^- and its half-life is by 6 orders of magnitude lower than for ^{235}U . This nuclide causes the major irregularity between the ^{232}Th and ^{238}U irradiation chains.

^d ^{248}Cm can already undergo spontaneous fission.

^e ^{249}Bk decays already by β^- .

^f ^{250}Cf is more stable than ^{244}Cm .

^gBecause of the repetitiveness, refer to the previous occurrence.

Neutron capture rate

The most trivial estimate of the neutron economy is represented by the simple sum of all capture rates in the irradiation chain. This sum can be compared with the average number of neutrons per fission $\bar{\nu}$, reduced by one neutron needed for next fission, to obtain the respective neutron excess or deficiency. It is only an approximate value, its accuracy can be increased by accounting also for the (n,2n) transmutation reaction, which is a source of extra neutrons.

Costs of synthetic actinides fission

Alternatively, the neutron economy can be assessed from the knowledge of the fission rate distribution between the nuclides in the irradiation chain. Each synthetic actinide in the irradiation chain is originated by consecutive transmutations of the primordial nuclide ^{232}Th or ^{238}U . Accordingly, the neutron costs of its creation can be obtained as the difference between its nucleon number and the original nucleon number (232 or 238). The ^{241}Pu creation in ^{238}U irradiation chain costs 3 neutrons ($241-238=3$). Therefore, 4 neutrons are at the end needed for its fission (see Table 2). For ^{237}Np in the same chain – 1 neutron is needed for creation ($237-238=-1$). The cost for its fission is thus 0 neutrons. Based on the knowledge of the fission rate distribution within the irradiation chain the total neutron costs can be obtained. This method is also only approximate. Since many of the nuclides are decaying by α decay, the four nucleons lost in each decay should be accounted for in such a balance.

Neutron balance of the irradiation chain

The overall neutron balance n_{B1} of the actinides chain can be obtained from the average number of neutrons per fission $\bar{\nu}$, reduced by one neutron needed for next fission, and the sum of normalized capture rates C_i and $(n,2n)_i$ rates of a given nuclide i :

$$n_{B1} = \bar{\nu} - 1 - \sum_i C_i + \sum_i (n, 2n)_i$$

An alternative neutron balance n_{B2} can be estimated from the fission rate distribution F_i between the nuclides in the irradiation chain and from the normalized α decay reaction rate:

$$n_{B2} = \bar{\nu} - \sum_i F_i n_i - 4 \sum_i \alpha_i$$

Table 2 Neutron cost of creation and fission for selected actinide nuclides in ^{232}Th and ^{238}U irradiation chains.

Nuclides chain		Position	Protons (<i>p</i>)	Neutrons (<i>n</i>)	Fissile by thermal neutrons	Absolute neutron cost to create	Absolute neutron cost to fission
1	2						
^{232}Th	^{238}U	+0p,+0n	even	even	not	0	1
^{233}U	^{239}Pu	+2p,-1n	even	odd	yes	1	2
^{234}U	^{240}Pu	+2p,+0n	even	even	not	2	3
^{235}U	^{241}Pu	+2p,+1n	even	odd	yes	3	4
^{236}U	^{242}Pu	+2p,+2n	even	even	not	4	5
^{237}Np	^{243}Am	+3p,+2n	odd	even	not	5	6
^{238}Pu	^{244}Cm	+4p,+2n	even	even	not	6	7
^{239}Pu	^{245}Cm	+4p,+3n	even	odd	yes	7	8

^{241}Pu	^{247}Cm	+4p,+5n	even	odd	yes	9	10
^{245}Cm	^{251}Cf	+6p,+7n	even	odd	yes	13	14

where n_i is the number of neutrons needed for fission of nuclide i (see Table 2) and the product $F_i n_i$ represents the fission costs, neutron costs to create and fission the nuclide. The trivial neutron balance for the four irradiation chains in Figs. 3–6 is illustrated in Table 3. Here it must be stressed, that the result in Table 3 refer only to the neutron balance of the actinides. The overall neutron economy of a reactor will depend also on the capture rate of structural materials, coolants and moderators and on the neutron leakage from the reactor core. Nonetheless, some basic statements can be made, based on the results in Table 3.

The ^{232}Th irradiation chain provides less neutrons per fission, around 2.5 neutrons. At the same time, its neutron capture rate is smaller. Hence it provides neutron excess in both thermal (0.12 neutrons) and fast (0.37 neutrons) spectra. The ^{238}U irradiation chain provides more neutrons per fission, around 2.9 neutrons. However, also the neutron capture rate is higher. The overall neutron excess is positive only in the fast spectrum (0.68 neutrons). In the thermal spectrum there is neutron deficiency (−0.18 neutrons) and the reactor cannot be operated with this fuel composition. Hence, self-sustaining breeding is not possible in thermal spectrum with ^{238}U . The major weakness of the ^{238}U irradiation chain is the lower fission rate of ^{239}Pu . Its major advantage, the higher average number of neutrons per fission, cannot compensate it in thermal spectrum. In ^{238}U uranium chain in graphite moderated MSR 1.08 and 0.54 neutrons are lost by ^{241}Pu and ^{245}Cm fission respectively. The capture rate of ^{239}Pu (35.8%), as a gateway for higher isotopes build-up, is $3 \times$ higher than the ^{233}U capture rate (10.6%) in the same reactor.

Radiotoxicity of the irradiation chain

Actinide alpha decay series

Synthetic actinide nuclides, in the discharged fuel from an open cycle practiced today or as the recycling losses in a closed cycle cause a long-term stewardship burden. They have very long half-lives (see Fig. 1) and the daughter products are also radioactive. All nuclides relevant for nuclear fuel cycle undergo either α or β^- decay. Alpha decay reduces number of nucleons by 4 whereas beta decay does not change it. This is the reason why all actinides decay in four separate decay series, which differ by number of nucleons i ($4i$, $4i + 1$, $4i + 2$, and $4i + 3$). These actinide alpha decay series are called: Thorium ($4i$), Neptunium ($4i + 1$), Uranium ($4i + 2$) and Actinium ($4i + 3$) series and they end with the first available stable nuclide, i.e., ^{208}Pb , ^{209}Bi , ^{206}Pb , and ^{207}Pb . The radiotoxicity should account for the contribution of all the nuclides in the entire decay series.

Since actinides with odd proton number are very unstable, especially when also having odd neutron number; practically all fissile nuclides are in Neptunium and Actinium series. The ^{232}Th and ^{238}U irradiation chains are shifted by 6 nucleons (+2p, +4n); hence, the nuclides in the same position within each chain decay through different series. The pairing term of the Weizsäcker formula cause some irregularity; however the half-lives for radioactive decay generally decrease with increasing nucleon number. The nuclides in the ^{238}U irradiation chains have thus shorter half-lives (see Table 1). At the same time, nuclides from this chain often decay through one of the ^{232}Th irradiation chain nuclides. Finally, evaluation of radiotoxicity is complex, because slowly decaying nuclide, e.g., ^{233}U , can provide low initial radiotoxicity; however, secondary peak can occur once the concentration of daughter product, e.g., ^{229}Th , will be stabilized. To illustrate this behavior, the radiotoxicity of selected nuclides caused by 10^{30} atoms is shown in Fig. 8. It represent the radiotoxicity caused by ingestion of the radioactive materials by human. The necessary coefficients have been adopted from (Soti et al., 2019). This figure shows radiotoxicity normalized to 10^{30} atoms. Accordingly, the values for some minor nuclides are exaggerated. However, it is identifying nuclides with substantial secondary peak: ^{233}U (^{233}Th), ^{234}U (^{238}Pu , ^{242}Am , $^{242\text{m}}\text{Am}$), and ^{237}Np (^{241}Pu). The case of ^{237}Np is particular because it decays through ^{233}U ; however, it has long half-life, which delays the ^{233}U secondary peak occurrence. It is obvious that nuclides with secondary peak are predominantly located in the ^{232}Th irradiation

Fig. 8 Evolution of ingestion radiotoxicity originated from 10^{30} atoms of selected nuclides in the Thorium (top-left), Neptunium (top-right), Uranium (bottom-left) and Actinium (bottom-right) series.

chain. For ^{235}U , ^{238}U , and ^{244}Pu , there is a late radiotoxicity increase caused by longer half-life of the daughter products ^{231}Pa , ^{234}U , and ^{240}Pu . However it is rather plateau than secondary peak. Similar radiotoxicity increase appears earlier for ^{232}Th , because its daughter product ^{238}Th has relatively short half-life. In all these cases, the radiotoxicity level is low and, with exception of ^{244}Pu related to the natural ore radiotoxicity.

Radiotoxicity of the ^{232}Th and ^{238}U irradiation chains

The ingestion radiotoxicity of 10^{30} atoms can be presented also for the actinides compositions from the four irradiation chains presented in Figs. 3–6. In the ^{232}Th irradiation chain, actinides composition in thermal spectrum provide slightly lower radiotoxicity. This is caused by lower absolute share of synthetic actinides. The two curves follow the same trend. In both cases a secondary peak occurs (see left Fig. 9). The radiotoxicity of ^{238}U irradiation chain is initially higher in thermal spectrum. The absolute share of synthetic actinides is lower in thermal spectrum also in this case. However, the difference is smaller and the thermal spectrum chain includes larger share of higher synthetic actinides nuclides. Since these decay faster, already earlier than 100 years after discharge the fast spectrum chain provides higher radiotoxicity. The secondary peak is absent in ^{238}U chain and the radiotoxicity continuously decreases (see right Fig. 9).

The results from Fig. 9 can be used to compare the relative radiotoxicity of the ^{232}Th and ^{238}U irradiation chains. Their ratio is presented in left Fig. 10 using logarithmic time scale and in right Fig. 10 using linear time scale. As expected, ^{232}Th chain provides initially up to $40\times$ lower radiotoxicity. Nonetheless, at longer time periods the secondary peak results in up to $20\times$ higher radiotoxicity. Accordingly, the final conclusion would be determined by time period of interest.

Synthetic actinides from the irradiated fuel become waste once they cannot be recycled and reused. In the open cycle they become waste by political decision not to recycle and reuse them. In the closed fuel cycle it is rather the recycling frequency and technology efficiency. There will be always some fraction of synthetic actinides in reprocessing losses. Therefore, the maximal resources utilization depends on the reprocessing losses as shown by Fig. 2. The radiotoxicity of synthetic actinides per unit of produced energy in the closed cycle depends on the resources utilization level. To provide an example, the initial radiotoxicity, just after shut down of the equilibrium reactor, per unit of produced energy is plotted in left Fig. 11 as a function of natural resources utilization. The radiotoxicity per unit of energy linearly decrease with increasing resources utilization. However, the

Fig. 9 Evolution of ingestion radiotoxicity originated from 10^{30} atoms of the ^{232}Th (left) and ^{238}U (right) irradiation chains in the graphite moderated MSR and MCFR.

Fig. 10 Evolution of the ratio between the ingestion radiotoxicity in ^{232}Th and ^{238}U irradiation chains in logarithmic (left) and linear (right) time scale.

Fig. 11 Dependency of the ingestion radiotoxicity per unit of produced energy on resources utilization (left) and reprocessing losses (right) for ^{232}Th and ^{238}U irradiation chains.

utilization depends on reprocessing losses and reprocessed fuel burnup in FIMA %. Hence, in the right Fig. 11 the same initial radiotoxicity per unit of energy is plotted as a function of reprocessing losses, assuming 5% FIMA burnup of the reprocessed fuel. Since the burnup is fixed in this example, the radiotoxicity per unit of produced energy grows linearly with increased reprocessing losses.

Summary

The nuclear fuel cycle relies on resources, which are not renewable. To fully utilize their potential self-sustaining breeding in closed cycle is needed, which is demanding from the neutron balance perspective. Not all reactor concepts are capable to achieve self-sustaining breeding and fully utilize the natural resources. Yet, many advanced reactors are capable of self-sustaining breeding and thus to produce energy from primordial ^{232}Th and ^{238}U nuclides, using synthetic fissile nuclides ^{233}U and ^{239}Pu as a kind of catalyzer. The fuel composition in a self-sustaining breeder operated in a closed cycle tends to converge to equilibrium composition. The type of irradiation chains and the reactor neutron spectrum determine the equilibrium composition.

These chains follow the line of stability and show a certain symmetry. This symmetry is explained in this article by the binding energy per nucleon in each of the chain nuclides. The properties of actinides nuclides are repeating in the nuclide chart with the step of 2 protons and 4 neutrons. The major difference between these chains is that almost all nuclides in the ^{232}Th irradiation chain have longer half-life for radioactive decay than their respective nuclides in the ^{238}U chain. This is an advantage from several perspectives. The available ^{232}Th resources are larger than those of ^{238}U thanks to the longer half-life of ^{232}Th . By the same token, the stewardship burden caused by high-level waste of the ^{232}Th irradiation chain is smaller in the short term. However, it also results in 11 times higher ^{233}Pa concentration than the respective ^{239}Np concentration. The increased parasitic neutron capture probability of ^{233}Pa slightly deteriorates the neutronic performance of ^{232}Th irradiation chain. Another difference is the irregular behavior of ^{241}Pu in the ^{238}U chain relative to ^{235}U , which is at the respective position in ^{232}Th irradiation chain: ^{241}Pu has a six orders of magnitude shorter half-life and decays by β^- decay, versus alpha decay of ^{235}U . The last important difference is that ^{233}U and ^{235}U as the major fissile nuclides in ^{232}Th chain have lower number of nucleons than the respective ^{239}Pu and ^{241}Pu in the ^{238}U chain, and therefore release, on average, less neutrons per fission.

The ^{232}Th and ^{238}U irradiation chains are presented in thermal and fast reactor spectra. Based on the nuclide concentrations and reaction rates, neutron economy is quantified and long term ingestion radiotoxicity assessed. The existing knowledge was confirmed that self-sustaining breeding in closed cycle is not possible in thermal spectrum reactors when fed with ^{238}U and questionable even when fed with ^{232}Th . In fast neutron spectrum the ^{238}U irradiation chain profits more from neutron spectrum hardening and performs better than the ^{232}Th irradiation chain.

The ingestion radiotoxicity is lower for ^{232}Th irradiation chain on relatively short time scale but higher on the long time scale. The longer half-lives provide initial advantage to the ^{232}Th irradiation chain, but this chain features a radiotoxicity peak several 10s of 1000s years following discharge. Beyond $\sim 20,000$ years the ^{238}U irradiation chain radiotoxicity is lower due to the shorter half-lives of its nuclides.

The general conclusion of this article is that self-sustaining breeding in closed cycle can be achieved with both primordial nuclides ^{232}Th and ^{238}U . The differences between the respective irradiation chains are relatively small and both nuclides represent valuable natural resource.

Glossary

Ac Actinides, elements with atomic numbers 89 to 103.

AcCl Label for tetra-chloride salt of actinides AcCl_4 .

Actinides Eigen-composition Stabilized actinides composition, an equilibrium composition which results from a long irradiation of one parent nuclide or their mixture. Necessary condition for the stabilization is that the mass of parent nuclide/s and the irradiation flux do not vary strongly. It is specific and inherent feature for every reactor and every parent nuclide/s and it represents the Eigen-vector of the respective Bateman equation.

B&B Breed-and-Burn; a mode of open cycle operation, where the fissile excess bred during irradiation is equal or higher than the discharged fissile mass after the irradiation. The reactor burns its own bred fuel. The discharged fuel does not need to be recycled and the fresh fuel does not need to contain primordial or synthetic fissile nuclides.

BG Breeding gain, $\text{BG} = \text{BR} - 1$.

BR Breeding ratio, it is ratio between breeding rate and fission rate. In a self-sustaining breeder $\text{BR} \geq 1$.

Breeding Transmutation of actinide nuclide initiated by neutron capture, which increases fission probability. Typically, primordial non-fissile (fertile) nuclides ^{232}Th and ^{238}U are transmuted into synthetic (man-made) fissile ^{233}U and ^{239}Pu .

Burnup Share of already fissioned actinides. It can be expressed in FIMA % (Fissions per Initial Metal Atom) or as energy released from given mass of actinides in MWd/kg (Megawatt days per kilogram). Since the energy per fission is approximately the same for all actinide nuclides, values expressed in these two units are proportional and roughly 10 times higher for the second unit.

Closed cycle A chain of process steps which is closed for the respective working medium. The medium, in nuclear fuel cycle the actinides, is recycled and does not extensively leave the chain.

Cross-section A measure of the probability that neutron will interact when flying by with the respective nucleus (microscopic cross-section) or when fling through with the respective nuclei concentration (macroscopic cross-section).

Equilibrium reactivity Reactivity provided by actinides Eigen-composition.

FPs Fission products, typically two fragments of actinides fission.

FLI Label for eutectic mixture of lithium fluoride salt and actinides tetra-fluoride salt LiF-AcF_4 .

FLIBE Label for eutectic mixture of lithium fluoride and beryllium di-fluoride with addition of actinides tetra-fluoride salt $\text{LiF-BeF}_2\text{-AcF}_4$.

Irradiation chain Series of consecutive transmutations and of the respective daughter products induced by neutron irradiation of one parent nuclide, e.g., ^{232}Th or ^{238}U . The radioactive decays of the daughter products are part of the chain.

MA Minor actinides, synthetic actinides originated by uranium transmutation (Np, Am, Cm and higher elements) without Pu, which is some time called major actinide.

NaCl Label for eutectic mixture of sodium chloride salt and actinides tetra-chloride salt NaCl-AcCl_4 .

Neutron economy Balance between neutron generation and neutron losses in a reactor. Good neutron economy has high neutron generation and small neutron losses by parasitic absorption and leakage from the reactor.

Open cycle A chain of process steps which is open for the respective working medium. The medium, in nuclear fuel cycle the actinides, is not recycled and leaves extensively the chain.

Primordial actinides Actinide nuclides, presumably originated by rapid neutron capture process during a supernova explosion, which have long enough half-life for radioactive decay to be still present on the earth.

Reactivity Reactivity is related to the effective (k_{eff}) or infinite (k_{inf}) neutron multiplication factor. Reactivity denotes the deviation from the self-sustaining fission chain reaction ($k = 1$), for which it is equal to zero. Reactor with negative reactivity ($k < 1$) cannot sustain the fission chain reaction. Positive reactivity ($k > 1$) means that there are more neutrons than needed for the self-sustaining fission chain reaction. From operational perspective, neutron absorber should compensate positive reactivity to control the chain reaction. From fuel cycle perspective, positive reactivity indicate that there are excess neutrons available for additional utilization by breeding or transmutations.

Self-sustaining breeding Breeding process where breeding rate $\geq$ fission rate, the mass of fissile synthetic nuclides is conserved in the reactor, and fission chain reaction is sustained solely by these synthetic nuclides. A long time-horizon is being considered in this article.

Subcritical/critical core A core that cannot/can sustain a fission chain-reaction.

Synthetic actinides Actinide nuclides originated, typically by neutron-induced transmutation, from primordial actinides. Synthetic nuclides are, by definition, a much broader group than minor actinides (MA) or trans-uranic elements. For thorium and uranium elements, both primordial and synthetic isotopes exist.

Waste Waste is unwanted side product, which is further unusable. In nuclear fuel cycle, synthetic actinides represent a side product, which is reusable. However, they can be declared as a waste by nuclear fuel cycle policy or when it is laborious to recover them, e.g., from reprocessing losses of certain fuel forms.

Introduction

This is the second of a series of three chapters that is dedicated to the identification of the advanced reactor technologies that are capable of self-sustaining breeding when fueled with either ^{232}Th or ^{238}U , and to the investigation of equilibrium fuel cycles properties and neutronics performance. The first chapter (Krepel, 2021a) characterizes the available fuel resources from the nuclear and reactor physics perspective. This second chapter determines the equilibrium fuel composition in advanced reactors and compares the basic features of the equilibrium fuel cycle and selected reactor neutronic performance characteristics at the equilibrium state. The third chapter (Krepel, 2021b) evaluates the fuel cycle performance from a neutronics perspective by means of the earlier

obtained equilibrium parameters. It provides an additional insight on why some advanced reactor concepts can act as self-sustaining breeders in closed or even open fuel cycle, while others do not.

Primordial actinide and self-sustaining breeding

The nuclear fuel cycle resources are not renewable and consist of three dominating primordial actinide nuclides: ^{235}U , ^{238}U and ^{232}Th . To fully utilize the potential of fertile ^{232}Th and ^{238}U , the self-sustaining breeding in closed cycle is needed. In such fuel cycle the primordial actinides are transmuted into synthetic fissile actinides ^{233}U and ^{239}Pu . This transmutation process is called breeding and reactors relying on this process are called breeders. Once originated, synthetic nuclides ^{239}Pu and ^{233}U can sustain the fission chain reaction and the breeding process itself. Accordingly, they practically act as a catalyzer for energy production from the primordial nuclides ^{238}U and ^{232}Th .

Simple fuel balance of the self-sustaining breeder requires that for each fissioned synthetic nucleus at least one transmutation of primordial nuclide takes place. Accordingly, up to two neutrons from each fission are needed; one for sustaining the chain reaction and one for maintaining of the fissile material balance. For each reactor and for each primordial nuclide, the composition of generated synthetic actinides tends to stabilize and reaches equilibrium concentration after sufficiently long neutron irradiation.

Irradiation chain and equilibrium cycle

Stabilized irradiation chain is obtained, when primordial nuclides ^{232}Th or ^{238}U are irradiated for sufficiently long time (Krepel, 2021a). The condition, necessary for this convergence, is that the primordial nuclide concentration and the irradiation flux do not vary. This condition is practically fulfilled by the operation of a breeder in closed fuel cycle, where all actinides are recycled and solely ^{232}Th or ^{238}U is refilled to the reactors as the feed material. The stabilized actinides composition is therefore also the Eigen-composition of the respective Bateman equation (Bateman, 1910). The so called equilibrium fuel cycle is a state, at which the self-sustaining breeder operated in closed cycle reaches the stabilized actinides composition. This equilibrium state is characterized by three variables: equilibrium fuel composition, equilibrium neutron spectrum and equilibrium multiplication factor.

The equilibrium fuel composition depends on the neutron spectrum and feed nuclide, here ^{232}Th or ^{238}U . The basic neutron spectrum type is determined by neutron scattering by the coolant and structural materials. However, it is also influenced by the equilibrium composition. Equilibrium spectrum and equilibrium composition together determine the equilibrium reactivity or actually equilibrium neutron multiplication factor (see Fig. 1). It is important to understand here that the multiplication factor does not affect the composition or spectrum. At the same time, reactivity excess or deficiency in equilibrium is the major indicator of the neutron economy and breeding capability.

From a historical perspective, the existence of an equilibrium state was revealed already during the pioneering time of nuclear energy, and the history is well described in Walter and Reynolds (1982). In a typical solid fuel fast breeder reactor, it takes five or six recyclings for plutonium vector stabilization (Journet et al., 1993). To enable concepts cross-comparison, a generalized Bateman equation was proposed and solved by a simplified approach in Salvatores et al. (2004). The term “equilibrium method” was also introduced in this reference. Inspired by this work, the EQL3D routine was developed (Krepel et al., 2008, 2012), which is a predecessor of the tool applied in the studies described in this article. The existence of an equilibrium state was obvious also for the developers of MSR concepts (MacPherson, 1985). Since it has liquid fuel, which enables continuous refueling and fission products removal, the knowledge of equilibrium was crucial for MSR. Several dedicated tools have been developed for MSR analyses in recent years, e.g., (Nuttin et al., 2005; Aufiero et al., 2013; Fiorina et al., 2013a; Seifried et al., 2013). The same is valid for bebble-bed HTR reactor, which also enables continuous removal and refueling of the fuel pebbles (Fratoni and Greenspan, 2007, 2010). Nowadays, there are many similar tools.

Fig. 1 Interdependency between neutron spectrum, fuel composition, and multiplication factor with indicated impact of the feed and scattering of coolant and structural materials. From Krepel J and Losa E (2019) Closed U-Pu and Th-U cycle in sixteen selected reactors: Comparison of major equilibrium features. *Annals of Nuclear Energy* 128: 341–357.

Objectives of this article

The objective of this article is to characterize the equilibrium fuel cycle for both the ^{232}Th and ^{238}U irradiation chains in 16 selected advanced reactors. The knowledge of the equilibrium state is of paramount importance for reactor performance evaluation, because it provides information:

- About the composition towards which the initial fuel tends to converge during irradiation;
- About the expected waste composition in both open and closed fuel cycles;
- Whether fuel parasitic neutron capture allows for establishing self-sustaining breeding;
- Whether there is sufficient neutron excess in the self-sustaining breeder for the utilization of legacy synthetic actinides (say, from LWR once-through fuel cycle) or for surplus fissile fuel breeding;
- About the rate of decrease of the legacy synthetic actinides concentration during irradiation.

This article is an extension and simplification of Krepel and Losa (2019), where details are provided. Selected aspect of this study have been published in Losa (2016), Krepel and Losa (2016, 2017) and Krepel et al. (2018).

Applied tool, assumptions and simulated reactors

The tool applied to more than 70 equilibrium calculations in this study is the Paul Scherrer Institut in-house procedure EQL0D (Hombourger et al., 2015, 2019). The simulations were relying on several simplifying assumptions, the major being Fission Products (FPs) neglect. The major impact of this simplification is an overestimation of the equilibrium reactivity. The selection of simulated reactors was aiming at covering all major neutron spectra and all major advanced reactor concepts. Accordingly, all Gen-IV reactor concepts described in this encyclopedia were included (Stanculescu, 2021).

Applied tool

The EQL0D procedure for burnup calculations is based on a MATLAB script. Historically there are three versions of the procedure: v1 is based on a MATLAB script and the deterministic ERANOS code (Rimpault, et al., 2002), and versions v2 and v3 that are based on a MATLAB script and the Monte Carlo code SERPENT 2 (Leppänen, 2013). The most advanced version v3 (Hombourger et al., 2016, 2019) adopts directly the burn-up matrix from the SERPENT code and applies the same method for the Bateman equation solution, including FPs. However, in this study the EQL0D v2 was applied (Hombourger, 2013; Losa, 2016), which relies on the MATLAB coupling with the SERPENT (see Fig. 2) code only through the actinide reaction rates. Hence, it cannot simulate FPs. As mentioned, the absence of FPs will result in equilibrium reactivity overestimation and slight spectrum softening. Whereas the spectral change can be neglected, the reactivity overestimation should be kept in mind.

The simulation of the ^{238}U and ^{232}Th irradiation used the ENDF/B-VII.0 nuclear data library (Chadwick, et al., 2006) and the SERPENT 2 code version was 2.1.23. The convergence of fuel composition was obtained after several iterations between the MATLAB burnup solver and the SERPENT code that generated spectrum-averaged cross-section for use in the burnup calculations. 20,000 source particles, 2000 active cycles, and 100 inactive cycles were used in the SERPENT calculations. The Monte Carlo nature of the code introduced issues with data noise. Its impact was not extensively evaluated for the EQL0D v2 version. Nevertheless, to minimize the oscillations relaxation between iterations was applied and relative mass change of ^{246}Cm smaller than 10^{-6} was used as a convergence criterion.

Fig. 2 Flow chart of EQL0D v2 routine. From Krepel J and Losa E (2019) Closed U-Pu and Th-U cycle in sixteen selected reactors: Comparison of major equilibrium features. *Annals of Nuclear Energy* 128: 341–357.

Assumptions

With the objective of this article being the comparison of the basic equilibrium features of the ^{232}Th and ^{238}U irradiation chains in advanced reactors, the results assembled here are based on three major assumptions:

- (1) The amplitude of the neutron flux, in which the fuel is irradiated, is determined by the specific power. It is unimportant for the fuel composition convergence if the core is subcritical or supercritical.
- (2) Each fission results in refilling of one respective ^{238}U or ^{232}Th atom, and FPs, as mentioned, are neglected. With this assumption, the usual composition variations during irradiation, cooling, and reprocessing stages are avoided.
- (3) Neutron leakage is not accounted for. The core is simulated only on the assembly level with reflective boundary conditions.

The first assumption assures that equilibrium state is achieved independent from the multiplication factor. The second and third assumptions simplify the modeling; however, they also result in equilibrium reactivity over-prediction. Presence of FPs and of neutron leakage will definitely reduce the equilibrium reactivity. It will also have an impact on the reactor spectrum and thus on the equilibrium fuel composition. However, this impact is secondary and the fuel compositions obtained by these assumptions are sufficiently representative for the needs of this study.

Simulated reactors

The advanced reactor concepts evaluated in this study follow the Gen-IV systems SFR, VHTR, LFR, GFR, MSR, and SCWR introduced in this encyclopedia in [Stanculescu \(2021\)](#), [Heidet \(2021\)](#), [Fütterer \(2021\)](#), [Alemberti \(2021\)](#), [Hatala \(2021\)](#), [Ignatiev \(2021\)](#) and [Huang and Zang \(2021\)](#). However, this study includes also alternative concept such as the FHR ([Fratoni, 2021](#)), chlorides salt based MCFR ([Krepel and Kramer, 2021](#)), and advanced LWR ([Shwageraus, 2021](#)). Moreover, to ensure that the examined reactor concepts are providing maximal variability of the neutron spectrum, at least one example is adopted from concepts considered in this encyclopedia, specifically: pressurized water cooled reactors ([Brown, 2021](#)), heavy water cooled reactors ([Nichita, 2021](#)), gas cooled reactors, water cooled graphite moderated reactors, and liquid metal-cooled reactors. The boiling water cooled reactors ([Hamon, 2021](#)) is not included as such, but covered by a parametric moderation study for LWR. In general, three basic principles were used for the selection:

- (1) All Gen-IV solid fuel reactors.
- (2) Most realistic MSR concepts.
- (3) Majority of existing power reactors.

As a result 16 reactor types were selected: 8 thermal and 8 fast; 6 based on liquid fuel in form of molten salts, and 10 featuring 4 different solid fuel types. The selected reactors and their labels used in results section are presented in [Table 1](#). It also includes the coolant density steps for the LWR parametric study. The assumed specific powers in [Table 1](#) are determined by three fuel cycle parameters: average irradiation time, burnup and fuel density, and refer to the ratio of volumetric power and specific actinides density, with unit W/g_{Ac} . The specific power for the MSR cases, where the core size is not always known, was adopted from LWR for fluoride salts and from LFR for chlorides salts, respectively. The higher specific power proposed for MFBR is adopted from [IGCAR \(2004\)](#). The lattices of the selected reactors are illustrated in [Fig. 3](#). Basically, there are five types of fuel: oxide pellets (LFR, SFR, LWR, RBMK, PHWR, HPLWR), TRISO coated particles in graphite pebbles in FHR and HTR, carbide pellets in GFR, zirconium based metallic fuel in MFBR, and molten salts in MSRs. The salts are further subdivided into chlorides and fluorides (see [Table 1](#)).

The solid fuel Gen-IV reactors include the sodium cooled reactor with both ceramic fuel (SFR) and metallic fuel (MFBR) options. The HTR is included together with its fluoride salt cooled version FHR. The other three reactors LFR, GFR, and SCWR, are included using one representative designs. Especially in case of SCWR, where HPLWR concept was selected, the choice is crucial, because the cladding material has strong impact on the core performance.

The MSR is rather a category of reactors than one single design; hence, the choice was driven by feasibility of the structural material, moderator, and fuel salt combinations. There are three major MSR classes: Graphite based MSRs, Homogeneous MSRs and Heterogeneous MSRs ([IAEA, 2021](#)). The latter class was excluded from this study. The reactors with heterogeneous layout rely on structural material to separate the fuel from dedicated coolant or non-graphite moderator. The major reason for their exclusion was the absence of publicly available data and some doubts about their technological maturity. However, a parametric study relevant to non-graphite moderated MSRs is presented in [Hombourger \(2018\)](#). The performance of heterogeneous fast MSRs is not addressed, as it is probable that the dedicated coolant and separation structural materials will increase both neutron scattering and capture reaction rates, and thus deteriorate the neutronics performance of this reactor type at the infinite lattice level considered in this study.

Only three MSR families were included in this lattice study: graphite moderated MSR, homogeneous fluoride fast MSFR, and homogenous chloride fast MCFR. Two fluoride and two chloride salts have been considered as the fuel carrier: $^7\text{LiF-AcF}_4$ and $^7\text{LiF-BeF}_2\text{-AcF}_4$ labelled as FLI and FLIBE and $\text{Na}^{37}\text{Cl-Ac}^{37}\text{Cl}_4$ and $\text{Ac}^{37}\text{Cl}_4$ labelled as NaCl and AcCl, respectively. The practical applicability of AcCl salt is rather hypothetical. The UCl_4 has reasonable melting temperature but is unstable; on the contrary, the stable UCl_3 has a high melting point. Since it is still much lower than the melting point of metallic actinides, AcCl was included in the study as a hypothetical actinide carrier delivering maximum performance. The selected salts are the best performing representatives from the neutronics perspective ([Hombourger, 2018](#)). For the graphite moderated MSR, the salt channel radius of 5 cm and the lattice geometry was adopted from [Hombourger et al. \(2016\)](#) using the case with 15% salt fraction ([Rosenthal, et al., 1971](#); [Krepel, et al., 2014](#)).

Table 1 Parameters of 16 simulated reactors and cases for the parametric study (Krepel and Losa, 2019).

Reactor name	Label	Fuel design adopted from (reference)	Fuel type	Specific power (W/g _{Ac})
<i>Solid fuel fast reactors</i>				
European lead system	LFR	Consortium of EU FP7 LEADER project (Artioli et al., 2009; Krepel et al., 2012)	Oxide	54.8
European sodium fast reactor	SFR	Consortium of EU FP7 ESFR project (Buiron, et al., 2007; Krepel et al., 2012)	Oxide	48.8
Gas cooled fast reactor	GFR	Consortium of EU FP7 GoFastR project (Bosq et al., 2006; Perkó et al., 2015)	Carbide	40.1

Since the study is limited to lattice calculations, the multi-zone cores in this assessment are represented only by one zone. This is also the reason why only one representative zone was selected for HPLWR and why Boiling Water Reactor (BWR) was excluded. It has flooded part, which performs similarly as Pressurized Water Reactor (PWR) and voided part with much harder spectrum. Nonetheless, the parametric moderation study provides certain insight for possible BWR performance. The third most abundant reactor type, PHWR, was included in this study, but the Gas Cooled Heavy Water Reactor (GCHWR) was not. The graphite moderated light water cooled RBMK was included; however, the CO₂ cooled Advanced Gas cooled Reactor (AGR) was not included. Whereas GCHWR is not operated anymore, the AGR exclusion is not scientifically justified and it is arguably the major reactor spectrum type missing in this comparison.

Equilibrium neutron spectrum

Equilibrium neutron spectrum is one of the three characteristics of the Eigen-state (the solution of the Bateman equations). The spectrum and the equilibrium fuel composition mutually influence each other (see Fig. 1). The initial and equilibrium fuel compositions provide different spectra. For dedicated U-Pu breeders the initial fissile load consists of plutonium from irradiated LWR fuel and the difference is small. For dedicated Th-U breeders it is more complex, because the initial fissile fuel, plutonium or enriched uranium, is not extensively present in the thorium irradiation chain. The difference between initial and equilibrium spectrum is thus not negligible. Nevertheless, for the purposes of this study it is still quite small, because the spectrum is mostly shaped by scattering materials and major fertile nuclide. In reactors, initially using ^{235}U fissile fuel, the equilibrium spectrum differ. However, the differences are smaller than expected and it seems that the effect of scattering and capture cross-sections of the coolant and structural materials as well as of the fertile fuel play a dominant role in spectrum determination. Hence, the equilibrium neutron spectrum is discussed here as the first result, because it is rather spectrum which influences fuel composition than vice versa.

To understand the spectrum differences between the 16 selected reactor types and between the LWR parametric cases, each spectrum is graphically represented as a point in a 2D plot; where the x coordinate represents the relative share of thermal neutrons (0–1 eV) and the y coordinate the relative share of fast neutrons (0.1–20 MeV). The resulting plots for both the Th-U and U-Pu cycles are shown in Fig. 4. This figure is used for general spectrum discussion. For a more detailed discussion, refer to Krepel and Losa (2019).

All fast reactors included in this study have zero share of thermal neutrons in their spectra. Hence they are vertically aligned on a line $x = 0$ according to their share of fast neutrons. The MSFR with softest fast spectrum is the lowest point on this line. The softening is enhanced by beryllium presence. Surprisingly, the share of fast neutrons around 30–35% in MSFR spectrum is comparable to that in LWR. It seems that ^7Li and ^{19}F , even though not thermalizing extensively the neutrons, are slowing the neutrons out of the fast energy range due to their scattering cross-section resonances at relatively high energies. For the respective cross-sections and spectra, please refer to Fig. 2 from Krepel and Kramer (2021) and to Fig. 7 from Krepel and Losa (2019). Other fast reactors have at least 55% of fast neutrons in their spectra. The hardest spectrum with more than 70% of fast neutrons has MCFR based on the AcCl salt. There are no structural materials in this homogeneous reactor and the only non-fuel nuclide, ^{37}Cl , has quite a low scattering cross-section with narrow resonances and features a relatively high mass. Hence, it is not softening the spectrum like, for instance, ^{23}Na having lower mass and higher scattering cross-section with broader resonance. The three classical fast reactors, SFR, GFR, and LFR are located practically at the same spot. Of the fast reactors with solid fuel, only the MFBR has somewhat harder spectrum. Its fuel in metallic form, without light elements like O_2 in oxide fuel, poses higher actinides density; the heterogeneity effect is thus pronounced and Na scattering relatively weaker. The difference between the Th-U cycle and U-Pu cycle in this graphical representation is negligible for fast reactors. Only the MCFR core seems to have harder spectrum in the U-Pu cycle. It is probably related to the higher rate of direct ^{238}U fission, which reduces the overall absorption rate of actinides. For more detailed discussion, refer to Krepel and Losa (2019).

The thermal reactors included in this study are located in the bottom half of Fig. 4. They are scattered along the diagonal, because moderation simultaneously decreases the fast neutron share and increases the thermal neutron share. The thermal spectrum share ranges from 25% to 80%. The hypothetical diagonal line, connecting bottom left and upper right corners in Fig. 4, represents reactors with 20% share of neutrons in the intermediate energy range (1 eV–0.1 MeV). Close to this line are reactors with very hard spectrum as MCFR or with very soft spectrum as FHR and HTR. It seems that the majority of the neutrons in these reactors have one preferable energy range and the intermediate range is thus suppressed. Reactors using graphite, heavy water and light water as a moderator and light water as a coolant (RBMK, PHWR, LWR, and HPLWR) are almost equally distant from the diagonal

Fig. 4 Equilibrium spectra distribution in Th-U (left) and U-Pu (right) cycles.

line. The worst from this perspective are fluoride salt based MSR and MSFR. The high share of intermediate neutrons in MSR and MSFR can be caused by the above discussed features of ^7Li and ^{19}F . At the same time, it is codetermined by homogeneous dilution of actinides in the salt. The heterogeneity effect is thus strongly suppressed and fast neutrons fission is higher in LWR than in MSFR or MSR.

The FHR and HTR are the two reactors with the lowest specific fuel density and fuel-to-moderator ratio in this study. In addition, they are designed for uranium with enrichment between 10–20%; but the equilibrium fuel composition includes only 0.5% or 1.5% of fissile nuclides for the U-Pu or Th-U fuel cycle, respectively. The total cross-section of actinides is thus very low and more neutrons are in the thermal equilibrium with the moderator than in the slowing down process. The presence of cooling salt in FHR case introduces additional parasitic neutron captures. As a consequence, FHR is less sensitive than HTR to the remarkable difference of synthetic actinides share between the Th-U and U-Pu cycles. The FHR and MSR-FLIBE are composed from the same elements; however, they differ in salt volumetric share and actinides specific density.

The LWR parametric study practically connects the solid fuel fast reactors with the LWR point. Light water moderated reactors (LWR and HPLWR) have specific fuel density comparable to fast reactors, and the fast neutrons share in their spectra is slightly higher than the thermal neutrons share. In heavy water moderated and light water cooled PHWR the proportions are the same. The remaining reactors are moderated by graphite, and the thermal neutron share dominates. The position of these reactors in the chart depends on fuel-to-moderator ratio, where the lower specific fuel density results in softer spectrum. In the RBMK case it is partly biased by the light water coolant. In [Hombourger et al. \(2015\)](#) and [Hombourger \(2018\)](#) another parametric study was performed with EQLOD v3 for graphite moderated MSR operated in the Th-U closed fuel cycle. The results of this study practically linearly span from MSFR through MSR towards FHR. The highest reactivity in the moderated area was obtained for the 15% salt share in the core and 5 cm channel radius; the case which was adopted for the present study.

Equilibrium fuel composition

The second major feature of the equilibrium state is the fuel composition. It represents a state to which every non-equilibrium fuel composition evolves during irradiation. It also determines the waste composition from reprocessing losses. Furthermore, together with the equilibrium spectrum, it determines the equilibrium reactivity.

Sixteen reactors comparison study

The equilibrium fuel composition for each of the 16 selected reactors and for each fuel cycle is presented in [Fig. 5](#) using masses relative to the major fissile nuclides, i.e., ^{233}U or ^{239}Pu . Accordingly, these two nuclides are not plotted in [Fig. 5](#) and the related discussion refers only to other synthetic actinides. The results for both cycles in [Fig. 5](#) are further divided into thermal and fast reactors charts. This division is driven solely by the different scale needed for thermal reactors in the U-Pu cycle. Since the simulation assumes continuous refueling of fertile feed, all nuclide masses are constant. For each nuclide the creation and destruction rates are in balance. The reactor spectrum type determines the reaction probabilities and these probabilities dictate the equilibrium mass of each nuclide. In all fast reactor cases, the synthetic actinides share is below 1. The only exception is MSFR with the softest fast spectrum in the U-Pu cycle.

In the Th-U cycle the synthetic actinides share is close to 1 also for thermal reactors. This is actually the reason why the Th-U cycle can be considered for thermal breeder reactors. It is the consequence of ^{233}U low capture probability, which stays around 10% of total fission rate also in thermal spectrum. The respective ^{239}Pu capture probability in thermal spectrum is roughly 3x higher, refer to [Krepel \(2021a\)](#). Hence, also the creation rate of higher nuclides is 3x higher in the ^{238}U irradiation chain than in the ^{232}Th irradiation chain.

In the Th-U cycle, a slightly higher share of synthetic actinides can be seen for HTR and FHR. These two reactors have the highest specific power. Accordingly, rate of synthetic actinides creation is influenced by increased fraction of ^{233}Pa and its transmutation into ^{234}U . Since the ^{233}Pa amount is proportional to specific power, this effect can be seen in smaller scale also for MFBR, where the synthetic actinides share is one of the lowest between fast reactors in the U-Pu cycle, but one of the highest in the Th-U cycle. Obviously, ^{239}Np with 11x shorter half-life for radioactive decay, refer to Table 1 from [Krepel \(2021a\)](#), does not affect the ^{240}Pu mass in the same manner as ^{233}Pa affects the ^{234}U mass.

In the U-Pu cycle the relative synthetic actinides amount in thermal reactors ranges from 4 to 12. Due to the energy dependent ^{239}Pu capture probability, this fuel cycle is much more sensitive to spectrum variation. Accordingly, for majority of thermal reactors the equilibrium fuel composition alone (not accounting for parasitic absorptions by FPs, coolant and structural materials) has too high parasitic capture and results in negative reactivity.

The relative masses of other synthetic actinides in [Fig. 5](#) are useful for the neutron balance considerations ([Krepel and Losa, 2019](#)). However, for other fuel cycle features, as for instance the radiotoxicity due to reprocessing losses, the absolute share of main fissile nuclide and of other synthetic actinides are more relevant. According to [Fig. 6](#), the main fissile nuclide share of all actinides is $\sim 10\%$ in all fast reactors and in both fuel cycles. This ratio is determined by the respective capture and fission cross-sections in the fast neutron spectrum of the main fertile and fissile nuclides, respectively. The same ratio in thermal spectrum strongly differs between the fuel cycles. It is slightly less than 1.5% in Th-U cycle and 0.5% in the U-Pu cycle. The lower ratio in the U-Pu cycle is a consequence of higher ^{239}Pu fission cross-section and its resonance in the thermal energy range.

Fig. 5 Actinides mass related to the main fissile nuclide in Th-U (top) and U-Pu (bottom) cycles. From Krepel J and Losa E (2019) Closed U-Pu and Th-U cycle in sixteen selected reactors: Comparison of major equilibrium features. *Annals of Nuclear Energy* 128: 341–357.

The actinides parasitic neutron capture usually does not allow for breeding in thermal spectrum. Furthermore, these reactors are very sensitive to FPs accumulation (Krepel, 2021b). This is valid especially in the U-Pu fuel cycle, where the fissile actinides share is 3 times lower than in the Th-U fuel cycle. The share of fissile nuclides is given by the respective cross-sections, which are actually strongly co-determined by the neutron pairing effect. The ^{233}U and ^{239}Pu nuclei with odd neutrons are more eager to interact with neutrons (have bigger cross-sections and bigger fission chance) than ^{232}Th and ^{238}U nuclei with even neutrons (Krepel, 2021a).

Fig. 6 also shows that the absolute amount of other synthetic actinides is much lower in thermal spectrum, around 1.8% in the Th-U and 2.5% in the U-Pu fuel cycle. Only HTR and FHR, as the outliers, have somewhat higher synthetic actinides share, 2.5–3.5% in the Th-U cycle and 5.5% in the U-Pu cycle. For fast reactors, MSFR-FLI and MSFR-FLIBE are the outliers. The second named has the highest synthetic actinides share of 10% and 18% in the Th-U and U-Pu cycle, respectively. In other fast reactors this share is around 7% in the Th-U and 9% in the U-Pu cycle. Only the MCFR-AcCl spectrum is sufficiently hard so that synthetic actinides share of around 5% is the same in both fuel cycles. In all other cases the Th-U cycle feature a smaller synthetic actinides share than the U-Pu cycle. In general, fast reactors have 4x higher absolute share of synthetic actinides share than thermal reactors. Accordingly, should the same absolute share of legacy actinides be added to the equilibrium composition in all reactors, thermal cores will transmute it up to four times faster (Krepel and Losa, 2016). However, as Fig. 5 or (Krepel, 2021b) indicates, it will cost more neutrons in the thermal spectrum.

The synthetic actinides share in the fuel determines their amount in recycling losses and together with the half-lives also the radiotoxicity. The share of synthetic actinides in both fuel cycles is up to four times lower in thermal reactors, and in all reactors it is also smaller for the Th-U cycle. Furthermore, this cycle profits from the fact that the synthetic actinides have longer half-lives than the respective nuclides in the U-Pu cycle. Thus the radiotoxicity is typically lower at the early stage for the Th-U cycle. However, as a consequence of the longer half-lives, a secondary peak may occur for the Th-U cycle and the U-Pu cycle may provide lower radiotoxicity in the longer term (Krepel, 2021a).

Fig. 6 Actinides relative composition in Th-U (top) and U-Pu (bottom) cycles.

LWR parametric moderation study

The high fission-to-capture probability of ^{233}U over a wide energy range in the Th-U cycle is well illustrated by the LWR moderation study. In this study, the water moderator is step-by-step removed from the reactor. The synthetic actinides share related to the ^{233}U mass stays constant at 1.1 level (see top Fig. 7) up to about 30% moderator density. From about 20% moderation, with water being almost completely removed, and the neutron spectrum getting very hard, the synthetic actinides share related to ^{233}U drops down to 0.6. In the U-Pu cycle, the variable ^{239}Pu fission-to-capture probability causes gradual drop of the ratio between synthetic actinides and the main fissile nuclide ^{239}Pu from 5 at full moderation to 1.1 at 50% moderation. Then there is a plateau, or even slight increase, and only the unmoderated case (0% water density) drops below this ratio being equal to unity (see bottom Fig. 7).

The relative masses in Fig. 7 mirror the fission-to-capture probability of ^{233}U and ^{239}Pu . The absolute shares of main fissile nuclides and of other synthetic actinides, presented in Fig. 8, are rather determined by the respective capture and fission cross-sections of the main fertile and fissile nuclides. The variation of fissile share with moderation has a similar tendency for both the Th-U and U-Pu fuel cycles, but it is not the same. The share of main fissile nuclide is $\sim 10\%$ in fast spectrum (0% moderation) for both cycles. It drops to 3% at 25–30% moderator density in the Th-U cycle, and at 40–45% moderator density in the U-Pu cycle. At 100% moderation the share is around 1.5% in Th-U cycle and 0.5% in the U-Pu cycle. In the thermal spectrum (70–100% moderation), the total amount of synthetic actinides is the same for both cycles, or even slightly lower for the U-Pu cycle. However, the split between the main fissile and the other synthetic actinides is different in the two fuel cycles.

Fig. 7 Actinides mass related to the main fissile nuclide in Th-U (top) and U-Pu (bottom) cycles for the LWR parametric moderation study.

Equilibrium multiplication factor

The equilibrium multiplication factor is the major indicator for the neutron economy. Since the fuel composition is stabilized and does not evolve during irradiation, all simulated reactors act as self-sustaining breeders. Nonetheless, not all reactor can reach criticality with the equilibrium fuel composition. Accordingly, the respective equilibrium reactivity is indication of the capability of the reactor to be operated as a self-sustaining breeder. In [Krepel \(2021b\)](#) the reactors are classified based on this reactivity.

The infinite multiplication factor for the 16 simulated reactors follows the expected trend. Since the reactors are roughly sorted in [Fig. 9](#) by their spectrum, for both fuel cycles, there is an overall increase in slope from left to right as the reactivity grows with spectrum hardening. The increase is higher for the U-Pu cycle, due to its higher sensitivity to spectrum variation and its effect on synthetic actinides build up (see [Figs. 5 and 7](#)). The trend in [Fig. 9](#) is, however, perturbed by varying parasitic neutron captures of coolants and structural materials.

As expected, practically all thermal reactors do not have sufficient equilibrium reactivity to be operated as self-sustaining breeders. For the Th-U cycle, in which the synthetic actinides mass stays low even in thermal spectra, there are few thermal reactors with positive or close to zero reactivity. These reactors are moderated by low capture moderators like heavy water or graphite. However, it should be recalled that the values of neutron multiplication factors in [Fig. 9](#) were derived from infinite lattice calculations and with the neglect of FPs. Accordingly, the excess reactivity will be lower in reality. Potentially, also beryllium could act as

Fig. 8 Actinides relative composition in Th-U (top) and U-Pu (bottom) cycles for the LWR parametric moderation study.

Fig. 9 Equilibrium multiplication factor for Th-U and U-Pu cycles and 16 selected reactors.

low absorbing moderator, e.g., for MSR. Nonetheless, both heavy water and beryllium needs to be separated from the MSR fuel by structural materials, which may deteriorate the performance (Hombourger, 2018). Furthermore, even if breeding would be possible in thermal reactors, their fissile share (see Fig. 6) is small. Hence, they will be very sensitive to FPs buildup (Krepel, 2021b). It may result in prohibitively high fuel reprocessing frequency. The only reasonable option could be the MSR, in which the FPs can be continuously extracted from the liquid fuel. However, even in this case the need of fast FPs removal may prove being prohibitive.

In the thermal spectrum cases, there are two outlier systems, FHR and HPLWR, with very low multiplication factors. In HPLWR case it is caused by parasitic neutron capture of the stainless steel cladding, which is not suitable for thermal spectra. In FHR it is due to the interplay between the parasitic neutron capture of the fluoride salt coolant, its higher volumetric share in the core, and the very low specific fuel density. The same salt in MSR-FLIBE, with higher specific fuel density and lower salt volumetric share, provides reasonable multiplication factors.

The Th-U cycle performs better than the U-Pu cycle in thermal, and worse in fast neutron spectra. The turning point is the MSFR-FLI, where the performance is the same in both cycles. It features a spectrum, in which the lower average number of neutrons per fission and the lower synthetic actinides concentration in the Th-U cycle provide similar reactivity as the higher average number of neutrons per fission and the higher synthetic actinides concentration in the U-Pu cycle. The detailed decomposition and analysis of the Fig. 9 results is presented in Krepel and Losa (2019).

The LWR parametric study provides insight for the equilibrium reactivity transition between thermal and fast reactors. Fig. 10 confirms that the reactivity changes with spectrum variation are stronger for the U-Pu cycle. At the same time the Th-U cycle is very close to $k = 1$ even for nominal water density and become critical already around 80% of the moderator density. However, for water moderator densities below 30%, the reactivity increase in the U-Pu cycle is steeper, yielding reasonable high reactivity earlier than in the Th-U cycle. Fig. 10 also illustrates the option to breed in reactor cores cooled by steam or in the upper part of BWR cores in which the exit water density is around 5% of the nominal LWR water density. It may be possible to design a water-cooled breeder (Huang and Zang, 2021) using water densities between 35% and 5% of the nominal LWR value. Optionally, a breeder with water density below 5% can be proposed solely for the heat production. Since the required steam pressure and accordingly the temperature would be lower, also the heat exchange and maximal power density would be limited.

Core size estimate

By means of Fermi's theory of the bare thermal reactor the critical core size can be estimated from the knowledge of equilibrium multiplication factor and material properties of each reactor (Losa, 2016; Krepel and Losa, 2017). The latter are a measure of how transparent the reactor core is for the neutrons. Application of this theory provides only very rough estimate, because the impact of neutron reflector or blanket is not accounted for. At the same time, it is based on an overestimated equilibrium multiplication factor, with neglected FPs parasitic absorption. Accordingly, it can provide certain insights for the interplay between equilibrium reactivity and reactor transparency for the neutrons.

The estimated core radii of bare self-sustaining breeders are presented in Fig. 11. The graphite moderated MSRs have quite substantial core radius. To obtain realistic core size, blanket and/or reflector should surround the core and the FPs must be continuously removed from the core. Furthermore, the neutron balance should be improved by ^{233}Pa extraction from the molten salt. Its radioactive decay outside of the neutron flux will increase the ^{233}U and reduce the ^{234}U production rates (Krepel, 2021a).

Fig. 10 Equilibrium multiplication factor for Th-U and U-Pu cycles and the LWR parametric moderation study.

Fig. 11 Estimate of bare critical core radius for Th-U and U-Pu isobreeding fuel cycles.

Optionally, some of the synthetic actinides (e.g., ^{237}Np) may not be recycled to decrease their contribution to parasitic neutron captures. The PHWR displays a smaller core radius than the MSR, but it has a solid fuel. Continuous FPs separation and ^{233}Pa removal is thus not possible. The fuel reprocessing frequency would need to be quite high to minimize the FPs captures and achieve breeding.

The SFR seems to provide the best combination of equilibrium multiplication factor and core material properties for a compact breeder. Especially in the U-Pu cycle the core is quite small. On the other hand, the MCFR represents an example of imbalance between the parameters. It has the highest equilibrium multiplication factor (see Fig. 9) and (together with the HTR and FHR) is the most transparent core for the neutrons. As a result, the core radius of the self-sustaining MCFR breeder is the largest of the fast reactors.

The estimate of minimum core radius for the LWR parametric study shows an interesting trend. For the Th-U cycle there are two minima, one at 55% moderation and the second at 0% moderation. The equilibrium multiplication factor between 100% and 30% moderation in Fig. 10 is almost constant, with very tiny local maxima at 55% moderation; nonetheless, the core radius is very sensitive to the moderation values (Fig. 12). The second minimum at 0% is due to the steep increase in multiplication factor as water density decreases below $\sim 20\%$. However, the core radius at 55% moderation is still too big for practical application. Interesting cases with smaller core radius < 200 cm are obtained for the U-Pu cycle in the range of 20–0% moderation and for the Th-U cycle in the range of 5–0% moderation (which is, probably, not practical from the heat removal perspective).

Fig. 12 Estimate of bare core radius for Th-U and U-Pu isobreeding fuel cycles in the LWR moderation parametric study.

Equilibrium temperature coefficients

The equilibrium state can be evaluated also from a safety perspective. In this article, only the fuel and coolant temperature coefficients of reactivity have been evaluated. To obtain these coefficients, the respective material properties are perturbed as follows: temperature of the fuel is increased by 300 °C at constant density, and density of the coolant is reduced by 10% at constant temperature. This approach allows for separation of the temperature and density effects for cases with fluid fuel.

Fluid density change

In all cores, the fluid density reduction results in decrease of the fluid capture and scattering probabilities. Compared to other core materials, its relative importance is thus reduced. The only exceptions are the homogeneous MSFR and MCFR, where the core is exclusively filled by the fluid (that functions as both fuel and coolant). In this case, the fluid density change represents a global density reduction, and since an infinite lattice is simulated, it has no impact on the reactivity (results absent in Fig. 13). In reality fluid density reduction will increase neutron leakage from a finite core and provide a negative reactivity effect.

The reduced capture probability results always in positive reactivity. The reduced scattering probability induces spectrum hardening that can introduce positive or negative reactivity. In fast reactors it introduces a positive reactivity (Krepel et al., 2011). It reduces the neutron capture rate in the resonance area and it increases the fission rate above the resonance area. The induced positive reactivity is higher in the U-Pu cycle (see LFR, SFR, GFR, and MFBR in Fig. 12), because the slope of the respective fission cross-section is steeper with increasing neutron energy as shown by bottom Fig. 17 from Krepel and Losa (2019) and because the resonances of the capture cross-section start at higher energies in the U-Pu cycle (Shusterman, 2021). Consequently, the positive coolant density effect for fast reactors is stronger in the U-Pu cycle (Fiorina et al., 2013b).

In thermal reactors, where the fluid also moderates the neutrons, the reduced scattering probability introduces negative reactivity. Interplay between this negative reactivity and positive reactivity introduced by capture probability reduction is crucial for the safety of moderated reactors. The overall effect should be negative. Hence, moderated cores are usually designed to be under-moderated, so that the moderator density reduction results in negative reactivity as for instance in PHWR and LWR. In many thermal reactors: FHR, HTR, RBMK, PHWR and MSR, dedicated coolant fluid is used, which has only minor moderation function. Its density effect is thus dominated by the capture component and results in positive reactivity. For PHWR coolant the capture component only slightly dominates above the scattering component and the effect is slightly positive. Nonetheless, in reality the increased leakage rate will somewhat compensate for the reduced capture rate. In MSR the fluid includes fuel and its density reduction reduces the fuel-to-moderator ratio (Krepel et al., 2014). In some cores there are two fluids with separate moderation and cooling functions. For such cores two independent results are presented in Fig. 13.

In the HPLWR the results differ qualitatively between the Th-U and U-Pu cycles. However, a big difference between the fuel cycles can be seen also for FHR, PHWR, MSR-FLI and LWR. In the U-Pu cycle, ^{239}Pu fission cross-section has a large resonance at 0.3 eV. A similar but weaker resonance of ^{233}U fission cross-section in the Th-U cycle is located at 1.8 eV, as indicated by top Fig. 17 from Krepel and Losa (2019) and Shusterman (2021). Nonetheless, the ^{239}Pu resonance has higher amplitude, it is broader, preceded by cross-section suppression, and followed by larger cross-section than in the ^{233}U case. Accordingly, in the U-Pu cycle the negative moderation effect is stronger. This can be seen particularly by HPLWR, where the moderator is located in a dedicated central tube (see Fig. 3) and its density effect is dominated by capture rate in the Th-U cycle and the moderation effect in the U-Pu cycle. In

Fig. 13 Reactivity induced by 10% reduction of the fluid density for Th-U and U-Pu cycles. In PHWR and HPLWR cases the moderator and coolant densities were reduced independently. From Krepel J and Losa E (2019) Closed U-Pu and Th-U cycle in sixteen selected reactors: Comparison of major equilibrium features. *Annals of Nuclear Energy* 128: 341–357.

PHWR the coolant and moderator density effects have opposite sign. It seems that the reactor is under-moderated from moderator perspective and over moderated from coolant perspective.

The results for LWR moderation study shown in Fig. 14 combine all above discussed effects. At 0% moderation there is no fluid in the core and the respective fluid density effect is zero. In thermal spectrum the negative reactivity effect is much stronger in the U-Pu cycle. This effect is primarily dictated by the ^{239}Pu fission cross-section characteristics that is also responsible for the relatively small ^{239}Pu fraction in Fig. 8. To a certain extend there is a correlation in the thermal region (100–65% of nominal water density)—the bigger the fissile share presented in Fig. 8, the smaller is the fluid density effect in Fig. 14. Higher fissile share implies a lower fraction of the fissions in the thermal energy range. It becomes unimportant at moderation levels corresponding to 45–5% of nominal water density. In this region the U-Pu cycle features less negative and eventually positive coolant density effect, because of the enhanced fission probability induced by spectrum hardening.

Doppler effect

The fuel temperature increase results in so called Doppler effect, or actually broadening of cross-section resonances. Since the cross-section resonances of the fertile fuel dominate neutron capture, the Doppler effect always results in negative reactivity. The only exception, PHWR in the U-Pu cycle, will be discussed separately. Since the respective mechanisms differ between fast and thermal reactors, the absolute reactivity change is presented in Fig. 15.

Fig. 14 Reactivity induced by 10% reduction of the water density in the LWR parametric moderation study for Th-U and U-Pu cycles.

Fig. 15 Doppler reactivity effect induced by 300 °C fuel heat-up in Th-U and U-Pu cycles. From Krepel J and Losa E (2019) Closed U-Pu and Th-U cycle in sixteen selected reactors: Comparison of major equilibrium features. *Annals of Nuclear Energy* 128: 341–357.

In fast reactors only the low-energy tail of the neutron spectrum is in the resonance area. Moreover, the ^{232}Th resonances start later at lower energies than for ^{238}U . The Doppler effect in fast reactors is, in simplified way, composed of negative reactivity caused by the enhanced capture in resonances and of positive reactivity from spectrum hardening induced by this enhancement (Krepel et al., 2011). Since the U-Pu cycle profits more from spectrum hardening, its resulting Doppler effect is less negative in fast reactors. The only exception is the MCFR core which features the hardest spectrum. In this reactor there are almost no neutrons in the energy range of the ^{232}Th resonances so the respective Doppler effect is smaller than in the U-Pu fueled reactors.

In thermal reactors the Doppler effect reduces the neutrons resonance escape probability during the slowing-down process resulting in a reduction of thermal spectrum component. Both the increased resonance capture rate and the suppression of thermal spectrum result in negative reactivity. The magnitude of the Doppler effect in thermal reactors depends on the moderator properties and on the core heterogeneity. The latter effect is strong in all water moderated or cooled reactors including PHWR and RBMK. In these reactors the Doppler effect has medium amplitude and is stronger for the Th-U cycle. In reactors with very weak heterogeneity (FHR, HTR and MSR) the resonance escape probability for the neutrons during the slowing-down process plays much more important role and the respective Doppler effect is very strong especially for the U-Pu cycle. Nonetheless, it is rather a complex phenomenon which is also effected by the concentration of other synthetic actinides in the core.

The U-Pu cycle in PHWR core is an exception. It features a positive Doppler effect because the dedicated heavy-water moderator does not have cooling function and its temperature is kept low. The respective Maxwellian spectrum peaks at the lowest energy, see Fig. 7 from Krepel and Losa (2019). The large resonance of ^{239}Pu fission cross-section is close to this peak. At the same time, the heterogeneity effect is very strong in PHWR and the resonance broadening in epithermal area has thus a lower impact on neutron capture. As a result, the fission resonance broadening dominates in this core.

The variation of the Doppler effect with the water density for LWR parametric study is shown in Fig. 16. The dominant effect is resonance capture probability that peaks at intermediate water densities which feature epithermal neutron spectrum. For very hard spectrum, the Doppler effect is the weakest due to very small resonance capture probability. It is the most negative for the Th-U cycle around 25% water density because spectrum hardening has a smaller positive reactivity effect than for the U-Pu fuel cycle. For the Th-U cycle it is the most negative around 60–75% water density because of the ^{239}Pu fission cross-section characteristics.

Summary

To fully utilize natural resources in nuclear fission reactors, self-sustaining breeding in closed cycle is necessary. In this cycle the synthetic fissile nuclides ^{233}U and ^{239}Pu acts as kind of catalyzer for energy production from primordial ^{232}Th and ^{238}U nuclides. The repetitive fuel irradiation in a closed cycle results in the equilibrium fuel composition. When only the ^{232}Th or ^{238}U primordial nuclides are used as a feed fuel, the respective equilibrium fuel composition corresponds to the ^{232}Th or ^{238}U irradiation chain. In this article the basic features of the ^{232}Th and ^{238}U irradiation chains were compared for 16 selected reactors and certain insight was provided, why some of the advanced reactors are not capable to sustain the breeding process.

EQLOD v2 MATLAB script coupled to the SERPENT 2 code was used to obtain the equilibrium state by iterative procedure on an infinite lattice. The specific power was fixed at nominal value, and the irradiation of the actinides was independent from the multiplication factor. Hence, the equilibrium state was obtained also for subcritical reactors. Since the fuel composition slightly oscillates during different phases of the closed fuel cycle, one simplifying assumption was applied to obtain the constant equilibrium vector. The FPs were neglected and each fission directly resulted in addition of ^{232}Th or ^{238}U atom. With this assumption the results become

Fig. 16 Doppler reactivity effect induced by 300 °C fuel heat-up in the LWR parametric moderation study for Th-U and U-Pu cycles.

insensitive to the discharged fuel cooling time, irradiation time, reprocessing intensity and reprocessing losses. Hence, the equilibrium state depends only on the reactor specific power and core lattice geometry, composition, and temperature. In spite of the simplifications, the obtained equilibrium reactivities and actinides eigenvectors are representative for the respective reactor and many useful conclusions can be drawn.

Three major equilibrium properties were compared: excess reactivity, fuel composition, and neutron spectrum. The reactor types included in this study were selected so that all major spectrum types are covered. A LWR parametric moderation study was included to illustrate the evolution of equilibrium parameters between thermal and fast spectra. Even though the majority of the presented results is well known, this article offers a slightly different perspective for their interpretation. Moreover, the LWR parametric study provides valuable insights into the evolution of the equilibrium properties between thermal and fast reactors. Self-sustaining breeding is generally possible in fast reactors. In thermal reactors only the Th-U cycle provides positive reactivity, which, however, may not be sufficient.

The assessment of critical core radii, included in this article, is only indicative, because the FPs as well as blankets or reflectors are neglected. At the same time, this assessment nicely illustrates that self-sustaining breeding in closed cycle is nearly impossible in thermal reactors. Their neutron economy is so tight, that they can afford only negligible leakage. The resulting cores are thus very large. Furthermore, to minimize neutron losses due to FPs, prohibitively high fuel reprocessing frequency may be needed.

Among the fast reactors, the SFR seems to provide the best combination of equilibrium multiplication factor and core material properties for compact breeder. Especially in the U-Pu cycle the core is quite small. In contrary, MCFR represents an example of imbalance between the parameters. It has the highest equilibrium multiplication factor, on the one hand side, and it is the most transparent core for the neutrons, on the other. As a result, the core radius of self-sustaining MCFR breeder is the largest of the fast reactors.

Two safety related parameters, i.e., the fluid density and the fuel Doppler reactivity effects, have been evaluated. Both these effects compose of two phenomena. The fluid density effect consists of reduced fluid absorption and of spectral hardening caused by the reduced neutron scattering. The Doppler effect consists of increased absorption in resonances and of the resulting spectral shift. These effects have different amplitude and direction in different reactors.

The general conclusion of this article is that self-sustaining breeding in closed cycle can be achieved with both primordial nuclides ^{232}Th and ^{238}U practically in all fast reactors. The U-Pu cycle profits more from neutron spectrum hardening and outperforms the Th-U cycle in fast spectra. The self-sustaining breeding in closed cycle is nearly impossible in thermal reactors. Due to the lower ^{239}Pu fission probability in thermal reactors, the creation rate of higher synthetic actinides is roughly 3 times higher in the U-Pu cycle and the equilibrium fuel composition alone has prohibitively high parasitic capture. The respective fission probability of ^{233}U in the Th-U cycle is high in all spectra. It may allow for self-sustaining breeding in closed cycle in some particular thermal reactors.

Glossary

Ac Actinides, elements with atomic numbers 89 to 103.

AcCl Label for tetra-chloride salt of actinides AcCl_4 .

Actinides Eigen-composition Stabilized actinides composition, an equilibrium composition which results from a long irradiation of one parent nuclide or their mixture. Necessary condition for the stabilization is that the mass of parent nuclide/s and the irradiation flux do not vary strongly. It is specific and inherent feature for every reactor and every parent nuclide/s and it represents the Eigen-vector of the respective Bateman equation.

B&B Breed-and-Burn; a mode of open cycle operation, where the fissile excess bred during irradiation is equal or higher than the discharged fissile mass after the irradiation. The reactor burns its own bred fuel. The discharged fuel does not need to be recycled and the fresh fuel does not need to contain primordial or synthetic fissile nuclides.

BG Breeding gain, $\text{BG} = \text{BR} - 1$.

BR Breeding ratio, it is ratio between breeding rate and fission rate. In a self-sustaining breeder $\text{BR} \geq 1$.

Breeding Transmutation of actinide nuclide initiated by neutron capture, which increases fission probability. Typically, primordial non-fissile (fertile) nuclides ^{232}Th and ^{238}U are transmuted into synthetic (man-made) fissile ^{233}U and ^{239}Pu .

Burnup Share of already fissioned actinides. It can be expressed in FIMA % (Fissions per Initial Metal Atom) or as energy released from given mass of actinides in MWd/kg (Megawatt days per kilogram). Since the energy per fission is approximately the same for all actinide nuclides, values expressed in these two units are proportional and roughly 10 times higher for the second unit.

Closed cycle A chain of process steps which is closed for the respective working medium. The medium, in nuclear fuel cycle the actinides, is recycled and does not extensively leave the chain.

Cross-section A measure of the probability that neutron will interact when flying by with the respective nucleus (microscopic cross-section) or when fling through with the respective nuclei concentration (macroscopic cross-section).

Equilibrium reactivity Reactivity provided by actinides Eigen-composition.

FPs Fission products, typically two fragments of actinides fission.

FLI Label for eutectic mixture of lithium fluoride salt and actinides tetra-fluoride salt LiF-AcF_4 .

FLIBE Label for eutectic mixture of lithium fluoride and beryllium di-fluoride with addition of actinides tetra-fluoride salt $\text{LiF-BeF}_2\text{-AcF}_4$.

Irradiation chain Series of consecutive transmutations and of the respective daughter products induced by neutron irradiation of one parent nuclide, e.g., ^{232}Th or ^{238}U . The radioactive decays of the daughter products are part of the chain.

MA Minor actinides, synthetic actinides originated by uranium transmutation (Np, Am, Cm and higher elements) without Pu, which is some time called major actinide.

NaCl Label for eutectic mixture of sodium chloride salt and actinides tetra-chloride salt NaCl-AcCl_4 .

Neutron economy Balance between neutron generation and neutron losses in a reactor. Good neutron economy has high neutron generation and small neutron losses by parasitic absorption and leakage from the reactor.

Open cycle A chain of process steps which is open for the respective working medium. The medium, in nuclear fuel cycle the actinides, is not recycled and leaves extensively the chain.

Primordial actinides Actinide nuclides, presumably originated by rapid neutron capture process during a supernova explosion, which have long enough half-life for radioactive decay to be still present on the earth.

Reactivity Reactivity is related to the effective (k_{eff}) or infinite (k_{inf}) neutron multiplication factor. Reactivity denotes the deviation from the self-sustaining fission chain reaction ($k = 1$), for which it is equal to zero. Reactor with negative reactivity ($k < 1$) cannot sustain the fission chain reaction. Positive reactivity ($k > 1$) means that there are more neutrons than needed for the self-sustaining fission chain reaction. From operational perspective, neutron absorber should compensate positive reactivity to control the chain reaction. From fuel cycle perspective, positive reactivity indicate that there are excess neutrons available for additional utilization by breeding or transmutations.

Self-sustaining breeding Breeding process where breeding rate $\geq$ fission rate, the mass of fissile synthetic nuclides is conserved in the reactor, and fission chain reaction is sustained solely by these synthetic nuclides. A long time-horizon is being considered in this article.

Subcritical/critical core A core that cannot/can sustain a fission chain-reaction.

Synthetic actinides Actinide nuclides originated, typically by neutron-induced transmutation, from primordial actinides.

Synthetic nuclides are, by definition, a much broader group than minor actinides (MA) or trans-uranic elements. For thorium and uranium elements, both primordial and synthetic isotopes exist.

Waste Waste is unwanted side product, which is further unusable. In nuclear fuel cycle, synthetic actinides represent a side product, which is reusable. However, they can be declared as a waste by nuclear fuel cycle policy or when it is laborious to recover them, e.g., from reprocessing losses of certain fuel forms.

Introduction

This is the third of a series of three chapters that is dedicated to the identification of the advanced reactor technologies that are capable of self-sustaining breeding when fueled with either ^{232}Th or ^{238}U , and to the investigation of equilibrium fuel cycles

properties and neutronics performance. The first chapter (Krepel, 2021) characterizes the available fuel resources from the nuclear and reactor physics perspective. The second chapter (Krepel and Losa, 2021) determines the equilibrium fuel composition in advanced reactors and compares the basic features of the equilibrium fuel cycle and selected reactor neutronic performance characteristics at the equilibrium state. This third chapter evaluates the fuel cycle performance from a neutronics perspective by means of the earlier obtained equilibrium parameters. It provides an additional insight on why some advanced reactor concepts can act as self-sustaining breeders in a closed or even an open cycle, while others do not.

Nuclear fuel cycle

The purpose of the nuclear fuel cycle, and of nuclear reactors as such, is energy production in two major forms: electricity and heat. The nuclear fuel cycle can be perceived from different perspectives. From a cosmological perspective, the nuclear fuel cycle consists of: first generation star formation following the big-bang (Garcia, 2021), supernova explosions of such first generation stars, ensuing second generation stars and planets formation, and finally primordial actinides utilization on planet Earth by mankind. Hence, the nuclear fuel resources are not renewable, and our aim should be to maximize their utilization with minimal waste production. From the more classical perspective, the nuclear fuel cycle includes stages before the irradiation: exploration, mining, milling, conversion, enrichment and fabrication (Crawford, 2021), the irradiation stage itself, and stages after the irradiation: interim storage, transportation, reprocessing, transmutation and waste disposal (Glatz, 2021). This article focuses solely on the irradiation phase. However, it has implications also for the other phases. For instance, the product of exploration, mining, milling and conversion is natural uranium. Based on the current irradiation scheme, we utilize less than 1% of the mined material, while 80% is stored in form of depleted uranium as the residuum from enrichment process, and 19% is discharged with the irradiated fuel. Higher utilization of the natural uranium resource will reduce the environmental impact, per unit of produced energy, of both uranium mining and enrichment.

Fuel cycle performance parameters

From the irradiation perspective, the major fuel cycle performance parameters are:

- breeding capability,
- achievable burnup,
- initial fissile mass,
- means of criticality maintenance, and
- transmutation capability.

The neutron economy is not listed as a standalone performance parameter. Nonetheless, since it effects all other parameters, it is analyzed in depth. Natural resources utilization is also not listed as a performance parameter. There is a big difference between the ^{235}U -fueled open cycle, where the natural uranium utilization does not exceed 1%, and the self-sustaining breeding in closed cycle (Wigeland, 2021), where the utilization of thorium and natural uranium can reach up to 95–98%. However, within these two fuel cycles types, the differences in terms of natural resources utilization are minimal. Accordingly, the breeding capability suffices as indicator for resources utilization, and the Breeding Ratio (BR) is used here as its measure.

However, there is one type of open cycle, where the utilization can be substantially larger than 1%. In so called breed-and-burn (B&B) open cycle mode, the natural uranium utilization can reach up to 20–35% (Qvist, 2021; Krepel and Kramer, 2021; Green-span, 2021). For this type of self-sustaining breeding in open cycle only the basic criteria for B&B operation are evaluated and discussed. Similarly, there are also safety related fuel cycle parameters. While these are not part of this study, the temperature coefficients of reactivity are addressed in Krepel and Losa (2021).

Compared reactor concepts

In this article the fuel cycle performance of 16 selected reactors is assessed. For details of their selection and their basic description, please refer to chapter (Krepel and Losa, 2021). The major criterion for the selection was to cover the majority of the advanced reactor concepts (Stanculescu, 2021) and the highest possible variety of the core neutron spectra. For readers' convenience the reactor labels are listed here in the same order used in the charts and tables:

FHR	Fluoride High temperature Reactor
HTR	High Temperature Reactor
RBMK	Reaktor Balshoi Moshnosti Kanalnyj (high-power graphite moderated water cooled channel-type reactor)
PHWR	Pressurized Heavy Water Reactor
MSR-FLIBE	Graphite moderated Molten Salt Reactor with fuel in form of eutectic mixture of lithium fluoride and beryllium di-fluoride with addition of actinides tetra-fluoride salts
MSR-FLI	Graphite moderated Molten Salt Reactor with fuel in form of eutectic mixture of lithium fluoride and actinides tetra-fluoride salts
HPLWR	High Performance Light Water Reactor

(Continued)

LWR	Light Water Reactor
MSFR-FLIBE	Molten Salt Fast Reactor with fuel in form of eutectic mixture lithium fluoride and beryllium di-fluoride with addition of actinides tetra-fluoride salts
MSFR-FLI	Molten Salt Fast Reactor with fuel in form of eutectic mixture of lithium fluoride and actinides tetra-fluoride salts
LFR	Lead cooled Fast Reactor
SFR	Sodium cooled Fast Reactor
GFR	Gas cooled Fast Reactor
MFBR	Metal fueled Fast Breeder Reactor
MCFR-NaCl	Molten Chlorides Fast Reactor with fuel in form of eutectic mixture of sodium chloride and actinides tetra-chloride salts
MCFR-AcCl	Molten Chlorides Fast Reactor with fuel in form of actinides tetra-chloride salts

The order of the reactors in the presented charts and tables was selected based on spectral index (Losa, 2016). For more discussion about equilibrium spectrum but also about assumptions and simulation tools refer to Krepel and Losa (2019, 2021).

Methods of fuel cycle performance assessment

Direct irradiation simulation

The basic method of fuel cycle performance evaluation is the direct irradiation simulation of an open cycle and comparison of the BR, achieved burnup, and differences between initial and irradiated fuel compositions. The major disadvantage of this method is that the initial fuel composition itself determines the BR and the respective reactor type (see Fig. 2). Furthermore, different initial compositions result in different achievable burnups. It is therefore hard to make general conclusions about the fuel cycle performance and inter-compare reactor types by means of the open cycle irradiation. It does not necessarily show where the fuel composition tends to converge, and whether the reactor would be critical at equilibrium. The BR obtained by direct irradiation simulation is often not sustainable, because not all daughter products concentrations are fully equalized. Unlike in the open cycle, explicit simulation of repetitive irradiation in a closed cycle is one of the most accurate methods to evaluate the ultimate fuel cycle performance (Krepel et al., 2012). Nonetheless, depending on the applied code, it is usually also the most time demanding simulation.

D-factors

Two more general methods have been proposed in OECD (2006) to evaluate actinides impact on the fuel cycle performance. Even though they were predominantly designed for synthetic actinides transmutation, they are also valid for the breeding. Both these methods rely in one or another way on the stabilized irradiation chain. The first method is based on so called D-factors. These factors represent the number of neutrons which are needed to ultimately fission one atom of a given nuclide. Accordingly, the knowledge of the respective irradiation chain is needed, because the D-factors account also for the neutron consumption by daughter products (Salvatores et al., 1994). The D-factors provide direct information about the neutron cost for the ultimate transmutation of given nuclide. Depending on the spectrum and nuclide type, D-factors can be positive (neutron consumption) or negative (neutron production). The D-factors thus quantify additional burden or gain for the neutron economy in a reactor loaded by external synthetic actinides. Since breeding is nothing else than a ^{232}Th or ^{238}U transmutation, the D-factors of ^{232}Th and ^{238}U actually indicate the neutron balance of a breeder. Since negative D-factor means that neutrons are produced, the ^{232}Th or ^{238}U D-factors should be negative to enable breeding (Krepel and Losa, 2016).

There are four basic Reactions (R) ongoing in nuclear reactor, where each of them can result in neutron production or consumption C^R :

1. $(n, 2n)$, producing one neutron ($C^1 = -1$)
2. neutron capture (n, γ) , consuming one neutron ($C^2 = 1$)
3. radioactive decay, no interaction with neutron ($C^3 = 0$)
4. fission (n, f) , consuming one and producing ν neutrons ($C^4 = 1 - \nu$)

The other interactions with neutrons were neglected in this evaluation. The D-factor for certain nuclide I is calculated from the knowledge of the irradiation chain and rely on the reaction probability P of the reaction type R which is multiplied by the above listed neutron consumptions C . These products should be summed up for all reactions, accounting also for the daughter products:

$$D_I = \sum_{R1=1}^4 P_{I \rightarrow I_{R1}} C_I^{R1} + \sum_{R1=1}^4 P_{I \rightarrow I_{R1}} \left(\sum_{R2=1}^4 P_{I_{R1} \rightarrow I_{R1,R2}} C_{I_{R1,R2}}^{R2} \right) + \sum_{R1=1}^4 P_{I \rightarrow I_{R1}} \left(\sum_{R2=1}^4 P_{I_{R1} \rightarrow I_{R1,R2}} \left(\sum_{R3=1}^4 P_{I_{R1,R2} \rightarrow I_{R1,R2,R3}} C_{I_{R1,R2,R3}}^{R3} \right) \right) + \dots \quad (1)$$

where, for instance, $I \rightarrow I_{R1}$ represent reactions R on a nuclide I of a type 1, 2, 3, or 4 as listed above, which leads to a daughter product I_{R1} . The fission reaction $R = 4$ terminates the transmutation chain. Reactions of the original nuclide I are presented by the first term in Eq. (1), the second term stands for the reactions of its daughters I_{R1} , and the third term for reaction of the daughters of daughters $I_{R1,R2}$ (see Fig. 1). Since one of the later daughter products $I_{R1,R2}$, $I_{R1,R2,R3}$, $I_{R1,R2,R3,R4}$, etc. may be identical with the

Fig. 1 Example of the D-factor algorithm application. Losa E (2016). *U-Pu and Th-U Fuel Cycle Closure*, PhD thesis. Prague: Czech Technical University in Prague, Department of Nuclear Reactors; Krepel J and Losa E (2016) Enumeration of static and dynamics neutron consumption D-factor for several selected reactors at equilibrium closed fuel cycle, *Proceedings of ICAPP 2016, San Francisco, USA*.

original nuclide I the equation represents an infinite series. For instance, the $(n, 2n)$ and (n, γ) reactions (see Fig. 1) cause that the nuclides I , $I_{2,1}$, and $I_{1,2}$ are identical. Fig. 1 also illustrates the plenitude of possible transmutation paths and the difficulty to compute the D-factors. Nonetheless, since all reactions are properly accounted for, the D-factors of ^{232}Th and ^{238}U accurately describe the neutron balance of a breeder.

Equilibrium method

The second method, proposed in OECD (2006) is actually the equilibrium method. It relies on the fact that if all fuel cycle parameters are fixed, recycling in closed cycle results in the equilibrium fuel composition. One of the fixed parameters is the composition of the fuel feed (make-up fuel). In OECD (2006) the primary aim was synthetic actinides transmutation, and thus the feed included them. This article focuses rather on the resources utilization, and the primordial actinide nuclides ^{232}Th or ^{238}U are exclusively used as the fuel feed. In this case a single irradiation chain represents the whole equilibrium fuel composition, and it is, therefore, the Eigen-vector of the respective Bateman equation (Bateman, 1910). For more detail about equilibrium fuel cycle simulation refer to Krepel and Losa (2021). This reference was also used to adopt the equilibrium fuel composition (stabilized actinides vector or actinides Eigen-composition) and the equilibrium multiplication factors.

One distinguished feature of the equilibrium fuel composition is that the concentrations of all actinides are constant. Per definition, the breeding and fission rates must be in balance for this composition. The rate of ^{232}Th or ^{238}U transmutation is thus equal to the fission rate of synthetic actinides. Hence, for each reactor there exists an equilibrium fuel composition for which $\text{BR} = 1$. However, not all reactors are critical with this fuel composition. Since there is a straightforward relation between BR and reactivity (Krepel et al., 2018), the equilibrium reactivity is used in this study to evaluate the breeding capability.

Breeding capability

Reactor classification

Breeding capability, a foremost fuel cycle performance parameter, defines whether a reactor can or cannot be operated as a self-sustaining breeder in closed cycle, which relies solely on fertile ^{232}Th or ^{238}U feed. It is determined by the neutron economy of the equilibrium state, particularly by the parasitic neutron capture of the equilibrium actinides composition. The breeding capability can be quantified as the ratio between breeding and fission reactions. This ratio is called Breeding Rate (BR), or alternatively also conversion ratio. In some cases the breeding capability is expressed as Breeding Gain (BG), where $\text{BG} = \text{BR} - 1$. In a self-sustaining breeder, where $\text{BR} \geq 1$, the fissile mass remains constant or slightly grows ($A \leq B$ in Fig. 2). In a reactor, where fission ($\text{BR} < 1$) or breeding ($\text{BR} > 1$) dominates, the fissile mass decreases or increases, respectively. However, only the equilibrium BR is relevant for the breeding capability assessment. BR of non-equilibrium fuel compositions does not need to be sustainable. Especially in the Th-U cycle, initial fissile load often consists of ^{233}U , ^{239}Pu , or highly enriched uranium, and $\text{BR} > 1$ can be obtained during the first irradiation cycle. Nonetheless, it does not mean that it is sustainable. Typically, in thermal spectrum systems, $\text{BR} > 1$ during the first irradiation cycle underestimates the parasitic neutron capture of synthetic actinides, e.g., ^{234}U , ^{236}U or ^{237}Np , which obviously did not yet converge to their equilibrium concentrations.

Equilibrium BR can be used to classify reactors into four categories: burner, converter, breeder and B&B (see Fig. 2). In a breeder it is at least equal to 1, in a converter it is below 1, and in a burner it should be at best 0. This would mean that there is no breeding process at all, what is nearly impossible. The BR border between burner and converter is not well defined and ranges from 0.5 to 0.9. Nevertheless, the major difference is that the fertile isotopes ^{232}Th and ^{238}U are usually avoided in burners dedicated to Minor Actinides (MA) transmutation. The minimal BR for a B&B reactor is around 1.5 (see Fig. 6), and thorium fueled reactors practically cannot be operated in B&B mode.

Neutron economy

Fig. 2 Illustration of reactor classification by breeding ratio for ^{238}U as a fertile isotope. A is the initial and B the discharged fissile actinides share.

Breeding ratio

The equilibrium multiplication factor k obtained in Krepel and Losa (2021) is smaller than one for some reactors. Using the simple relation from Krepel et al. (2018), BR or BG can be calculated from k and the average number of neutrons per fission $\bar{\nu}$ as follows:

$$BR \cong 1 + \bar{\nu} \frac{k - 1}{k} \quad \text{or} \quad BG \cong \bar{\nu} \frac{k - 1}{k} \quad (2)$$

The approximate relation in Eq. (2) was derived for the equilibrium state and its accuracy decreases with increasing distance of k from 1. For convenience the breeding capability will be discussed using BG. From the 16 selected concepts, there are only few thermal Th-U cycle reactors with positive or close to zero BG (see Fig. 3). Nonetheless, it should be recalled that the equilibrium multiplication factors, applied for this BG estimate, correspond to an infinite reactor without Fission Products (FPs). The infinite BG presented in Fig. 3, thus, represents hypothetical maximum and not realistic values. The neutron losses by leakage from finite core can be reduced by blanket and/or reflector addition. However, the parasitic neutron absorption by FPs cannot practically be suppressed, since it would result in prohibitively high fuel reprocessing frequencies in thermal breeders. The achievable burnup as the second fuel cycle parameter would be discussed in the next sub-chapter. However, MSR concepts with liquid fuel could potentially be considered as a reasonable thermal spectrum breeders. Since their fuel is liquid, continuous FPs removal strategies might offset high reprocessing frequency penalties. Furthermore, this would allow for removal of higher actinides and questionable separation of ^{233}Pa and its decay outside of the neutron flux to improve the neutron balance (see 3rd and 4th term of Eq. 4).

All fast reactors have positive BG. Only the MSFR-FLIBE with the softest fast spectra, see Fig. 4 from Krepel and Losa (2021), has close to zero but negative BG in the U-Pu cycle. For all other fast reactors BG is almost twice higher in the U-Pu cycle. BG as well as equilibrium multiplication factor are integral parameters and encompass also the impact of non-fuel materials in the core. Even though, non-fuel materials introduce a certain perturbation, it is clear that the U-Pu cycle profits more from the spectrum hardening as compared to the Th-U fuel cycle. Once the ^{239}Pu capture probability decreases in a hard spectrum, the higher average number of neutrons per fission starts to dominate. The Th-U fuel cycle is also performing better in a harder neutron spectrum. However, the

Fig. 3 Infinite breeding gain for Th-U and U-Pu cycles and 16 selected reactors.

trend is much milder, because the ^{233}U capture probability is generally low and less dependent on neutron spectrum. The BG in the Th-U fuel cycle is lower in fast reactors because of the ^{233}U lower average number of neutrons per fission.

Achievable burnup

Once the reactors are classified according to their breeding capability, the second most important performance parameter for the fuel cycle is the achievable burnup. In both open and closed cycles, higher burnup reduces the core reloading frequency and the need of fuel fabrication, transportation and optional reprocessing. Hence, it reduces the fuel cycle costs. Since the amount of synthetic actinides tends to stabilize during the irradiation, higher burnup in an open cycle results in lower waste amount per unit of produced energy. In a closed cycle, it decreases the reprocessing frequency and thus also reduces the waste amount, see Fig. 2 in Krepel (2021). From neutron economy perspective, the achievable burnup is determined by BR, initial fissile mass, and equilibrium fissile mass.

Fission products cumulation

The major issue of burnup is that the neutron economy, but also other fuel mechanical and chemical features, deteriorate during irradiation. In every reactor, FPs accrue during irradiation and increase the parasitic neutron capture. Ultimately, every reactor will become sub-critical if FPs would not be regularly removed. FPs impact on neutron economy depends on their concentration and neutron capture cross-section. Its relative strength is associated with the fissile actinides concentration and fission cross-section. Hence, the deterioration caused by FPs can be pronounced or suppressed by evolution of fissile actinides share and depends also on the absolute value of this share. For equilibrium fuel composition $\text{BR} = 1$, and the share of fissile actinides is constant. Should the initial fissile share be above or below the equilibrium one, the irradiation will result in its decrease or increase, respectively. This has strong implication for actinides parasitic capture itself, but also for the relative FPs strength. Majority of ^{235}U -fueled reactors use thermal spectrum and low enriched uranium. Hence, BR is around 0.2–0.5 and the fissile actinides share is strongly decreasing during the irradiation. Consequently, the relative importance of FPs concentrations and capture cross-sections is growing faster than the respective absolute values.

Impact of absolute fissile share

The absolute share of fissile actinides also indicates how sensitive the neutron economy will be to FPs buildup. The fissile share in the ^{232}Th irradiation chain is roughly 1.5% in thermal and 10% in fast reactors (see Fig. 4). A burnup (BU) of 5% FIMA implies that 5% of the actinides are fissioned. At the same time, the FPs mass corresponds to 300% of the fissile actinides mass in thermal and only to 50% in fast reactors. In the U-Pu cycle it is even more pronounced, burnup of 5% FIMA means that the FPs mass can be up to 14 times higher than the fissile mass (see Fig. 5). The higher fissile share is actually the major reason why fast reactors are less sensitive to FPs build up. However, it partly depends also on the ratio between FPs capture cross-section and actinides fission cross-sections, which is spectrum dependent. Even though, it is rather a hypothetical example, 1.5% of fissile share in discharged fuel and burnup of 5% FIMA represent reasonable values for typical LWR.

Fig. 4 Share of fissile actinides in the fuel for Th-U and U-Pu cycles and 16 selected reactors.

Fig. 5 Ratio between 5% FIMA burnup and fissile actinides share in the fuel for Th-U and U-Pu cycles and 16 selected reactors.

This study does not evaluate achievable burnup as such and it even neglects FPs. Nonetheless, for each reactor, the BR is being assessed and fissile actinides share is provided. In general, the foreseen burnup for fast breeder reactors is usually similar to their fissile actinide share in the core, i.e., around 10% FIMA. Nonetheless, 15–20% is achievable from a neutron economy perspective. Breeding in thermal reactors would likely not even allow for reaching burnup equal to the fissile fuel share.

It should not be forgotten, however, that a reactor core usually consists of several groups of fuel assemblies with different burnups to minimize the reactivity oscillations (see Fig. 8). The average FPs share in every core is thus roughly the half of final discharged burnup. Accordingly, for discharged burnup of 20% the average FPs share in the reactors would be 10%. Hence, it would be equal in this example to the fissile actinides share in fast reactors. The exceptions from this rule, are the reactors with liquid fuel (MSR, MSFR, and MCFR) where the fuel is homogeneously mixed, the effective FPs share in the core is averaged, and the final discharged burnup is equal to the average burnup. The achievable burnup in these reactors can be lower. At the same time, the liquid fuel allows for continuous FPs removal. Hence, it partly compensates the averaging effect.

Basic assessment of the B&B cycle

The neutron economy of a breeder is very tight, and the bred synthetic actinides must be recycled to maintain the fissile material balance. The only exception from this requirement are very strong breeders, where the fissile excess bred during the irradiation would be equal or higher than the discharged fissile mass after the irradiation. Since the bred excess is not necessary for the fissile mass conservation, these very strong breeders can self-sustain the breeding in open cycle in the B&B mode (Qvist, 2021). The name is derived from the fact that the loaded fuel does not need to contain fissile actinides; they are bred during the irradiation in the B&B reactor and suitable fraction of them fission in that reactor. The trivial condition for B&B reactor operation is based on the balance of bred synthetic actinides (Krepel et al., 2018). The amount of extra bred fissile synthetic actinides, in a period between two refuelings, should be equal or higher than the amount of fissile synthetic actinides (F_F) removed during the actual refueling:

$$F_F \leq BU \cdot BG \quad (3)$$

where BU is the burnup in absolute FIMA share and the product of BU and BG represent the extra bred amount of fissile synthetic actinides. The presence of burnup in Eq. (3) is also the reason why the B&B cycle assessment is placed after the achievable burnup subsection. This trivial condition for B&B reactor operation can be graphically presented for three particular fissile actinides contents in the core. These are 1%, 2% and 10% and correspond roughly to the equilibrium fissile actinides share in Fig. 4. In thermal reactors, with 1% or 2% of fissile actinides share in the respective U-Pu or Th-U cycle, the overall neutron economy does not allow for B&B operation. The required combination of BG and burnup is not achievable in thermal spectrum. The B&B cycle is possible only in fast reactors. Even though, the fissile actinides share of 10% shifts the respective curve in Fig. 6 higher, the required combination BG and burnup is still more realistic. Assuming burnup of 20% FIMA, BG of 0.5 would be needed for reactor with 10% share of fissile actinides. There are only four concepts with sufficiently high BG in Fig. 3, these are the two sodium cooled concepts and the two MCFR concepts. Since the MCFR concept with liquid fuel allows for partial FPs removal from the core, it can theoretically allow for higher burnup in the B&B open cycle mode (Krepel and Kramer, 2021).

Fig. 6 Relationship between breeding gain, discharged fuel burnup, and fissile share in discharged fuel to enable B&B reactor operation.

Initial fissile mass

As mentioned, nuclear reactors can be divided according to BR into four categories presented in Fig. 2. The breeder and the B&B reactor will, once started, maintain their own fissile mass constant and use only ^{232}Th and ^{238}U (in form of depleted or natural uranium) as the fertile feed. Since the self-sustaining breeder maintains its own fissile share, no matter if in a closed cycle with recycling or in an open B&B cycle, the initial fissile mass does not strongly differ from the equilibrium fissile mass.

The burner reactor is fueled with synthetic actinides, and its objective is maximum reduction of their amount. It should be at best operated in closed cycle. Hence, synthetic actinides represent its initial fuel in open cycle, as well as the feed in closed cycle.

Only converters are extensively operated in an open cycle. Their initial fuel is typically enriched uranium, and their purpose is energy production. The vast majority of ^{235}U -fueled converters has thermal neutron spectrum and cannot be operated as a breeder. The equilibrium share of fissile actinides in thermal reactors is low. In the ^{238}U chain, it is below 1% (see Fig. 4). Hence, it is quite similar to the ^{235}U share in natural uranium. Even though there are exceptions, neither natural uranium nor the ^{238}U irradiation chain can make thermal reactors critical. To be able to operate these reactors, but also to reach a reasonable burnup, the capture rate of ^{238}U needs to be suppressed by uranium enrichment. Since the equilibrium fissile share in ^{238}U chain is below 1%, the 5% ^{235}U enrichment will result in a more than five times lower ^{238}U capture rate. Accordingly, the BR in this simplified example will be roughly 0.2 for 5% enriched uranium.

The initial fissile mass, as well as the transition scenarios towards the equilibrium cycle, are not an objective of this study. For all reactors operated in a closed cycle, the initial fissile mass is determined by the equilibrium fissile share. To provide some insight, the specific density of the main fissile nuclide in the equilibrium state is shown in Fig. 7. It is only an indication of the initial fissile mass requirement. To assess the total masses, it should be multiplied by the approximate core volume (Krepel and Losa, 2021). Furthermore, for a converter operated in an open cycle, the initial fissile mass is correlated with the achievable burnup.

Fig. 7 Main fissile nuclide, i.e., ^{233}U or ^{239}Pu , specific density for Th-U and U-Pu cycles and 16 selected reactors.

Means of criticality maintenance

Means of criticality maintenance are relevant predominantly for the open cycle. In the ^{235}U -fueled reactors, the fission rate strongly dominates over the breeding, and the fissile mass is decreasing during the irradiation. As a consequence, the FPs impact on neutron economy is growing in both absolute and relative terms. To achieve reasonable burnup, the initial ^{238}U capture rate must be suppressed by uranium enrichment. This suppression exceeds the initial criticality needs and causes a huge reactivity excess. This excess needs to be compensated by neutron absorbers, which are either burnable or removable, e.g., control rods. They compensate the initial reactivity excess needed for high burnup and are gradually burned or removed. They are called burnable, because their capture cross-section is very high and their mass low. Hence, their capture rate is strongly decreasing with their transmutation. The primordial nuclides ^{232}Th and ^{238}U can be theoretically also considered as burnable absorbers. However, their capture cross-sections are rather small and absolute mass rather high. Accordingly, the capture rate change is too slow. Nonetheless, ^{232}Th performs slightly better from this perspective and in some reactors it may indeed act as burnable absorber, which is balancing the increasing mass of FPs (Krepel et al., 2015).

In fast reactors operated in a closed cycle or in an open B&B cycle, the fissile fuel share is roughly constant and usually around 10% (see Fig. 4). Nonetheless, the FPs buildup and the ^{232}Th or ^{238}U refilling induces need for regular fuel reloading. The FPs buildup and the actinides composition changes result in reactivity variation during irradiation. Hence, control rods are needed for their compensation. To illustrate these variations the results of a GFR sensitivity study Krepel et al. (2010) are presented in Fig. 8. In this simulation, the GFR was operated as a self-sustaining breeder in closed U-Pu cycle, and different stages of the fuel cycle (irradiation, cooling time before reprocessing, and reprocessing) were explicitly simulated. In the sensitivity study, the cooling time before reprocessing was altered. The objective of the study was to evaluate the impact of ^{241}Pu decay during the cooling period. Since the fissile nuclide ^{241}Pu decays into the fertile nuclide ^{241}Am , the cooling time was actually altering the ratio between fissile and fertile nuclides. Accordingly, the longer cooling time resulted in higher BG at the beginning of irradiation. Fig. 8 is thus prototypical for reactivity variations in a fast breeder reactor as a function of the initial BG.

The left hand side of Fig. 8 shows the reactivity variation caused by FPs buildup and actinide composition change during the irradiation using an one-batch approximation. In this case all assemblies are loaded, irradiated and unloaded together. On the right hand side of Fig. 8, the assemblies are divided into three groups and only one third is removed at a time. In both cases, the reactivity variations are minimal, when the initial BG is positive, and the reactivity firstly grows. This fact is underlined on the right hand side of Fig. 8, where the three-batch operation practically averages the curves from the left hand side. For the cases with highest initial BG, or actually longest cooling time, where the reactivity initially grows (left hand side of Fig. 8), the variation is minimal (bottom curves in right Fig. 8).

The reactivity variations presented above can be avoided in reactors where the FPs are being continuously removed and actinides continuously added to the core. This is the case for MSR, MSFR, MCFR with liquid fuel and for PHWR and HTR (FHR) with small fuel assemblies and online refueling strategy (during power operation). While criticality maintenance is not an objective of this study, it is worthwhile noting that self-sustaining breeders are expected to have much smaller reactivity variation during irradiation than an open cycle operated ^{235}U -fueled reactors. At best, the reactors should have small breeding ratio excess, so that the fissile mass is slightly increased at the beginning of the cycle and balances the subsequent decrease caused by FPs parasitic neutron capture.

Transmutation capability

Some of the advanced reactor concepts are dedicated to the minimization of legacy synthetic actinides. Their performance is thus measured by the transmutation capability. This is an ambivalent term, because even the breeding is a transmutation. Nonetheless, the transmutation refers here rather to the fission, which is the major option to reduce the long-term stewardship burden related to

Fig. 8 Neutron multiplication factor evolution during the irradiation in GFR in one-batch approximation (left) and three-batch simulation (right) as a function of fuel cooling time before reprocessing, which changes the initial BG.

synthetic actinides. Furthermore, some concepts are meant to combine both fuel breeding and legacy synthetic actinides transmutation objectives. The usual measure of the transmutation capability is the concentration reduction of selected actinides and the related neutron costs. The reduction can be expressed as the partial fission share of the legacy actinides. The neutron costs are evaluated here by the D-factors.

The fissioned share of legacy actinides in open cycle can be deduced from the difference between the loaded and discharged fuel. Necessary condition for successful transmutation is that the concentration of a given legacy actinide, assuming that it is irradiated together with either ^{232}Th or ^{238}U , is above its equilibrium concentration in the respective irradiation chain. The equilibrium fuel composition thus provides certain information about transmutation capability. For instance, based on the example in Fig. 3 from Krepel (2021), the ^{239}Pu share in the ^{232}Th irradiation chain is very small (0.007% of the fuel) and comparable to the ^{238}Pu and ^{242}Pu concentrations. The share of other plutonium nuclides or of americium and curium nuclides is even lower. This feature makes the ^{232}Th irradiation chain attractive for utilization of synthetic actinides originated from ^{238}U irradiation. In some reactor concepts, thorium is thus proposed as a semi-inert fuel matrix (Shwageraus 2021; Wigeland, 2021). The term semi-inert refers to the fact that ^{232}Th irradiation does not extensively generate synthetic nuclides, which are typical for the ^{238}U chain. Nonetheless, it produces its own synthetic nuclides, and the benefit of this solution should be carefully evaluated, refer to Fig. 10 from Krepel (2021).

In a closed cycle, where all fed actinides are ultimately fissioned, the transmutation rate of legacy actinides is equal to their share in the feed. There are concepts, where MA act as the sole feed in a closed cycle, and their irradiation partly results in fissile Pu buildup (Artioli et al., 2007). The BR can be above one for the respective MA feed (Krepel et al., 2009). This is the reason why only the equilibrium BR related to ^{232}Th or ^{238}U should be considered for the reactors classification given in Fig. 2.

Transmutation generates neutron excess or shortfall, which is represented by the D-factors. As shown by the example given in Fig. 9, the D-factors do not differ strongly between the Th-U and U-Pu cycles. However, they vary strongly with the neutron spectrum. Transmutation of ^{242}Pu can cost around 1 neutron in a thermal spectrum while providing 0.8 neutrons excess in a fast spectrum. The dynamics of transmutation depends on the specific power of the reactor and on the absorption cross-section of the transmuted nuclide. In Fig. 10 the absorption rate per 10^9 atoms of ^{242}Pu is shown. Obviously, the rate is higher in thermal spectra, because of the generally larger cross-section. At the same time, it is quite high also for the MFBR due to its high specific power. In general, the transmutation of legacy actinides costs less neutrons in fast neutron spectrum systems; however, it can be faster in thermal neutron spectrum.

Neutron economy

All fuel cycle performance parameters discussed above depend on the neutron economy. Nonetheless, the equilibrium multiplication factor or BG provide only one integral value for the overall neutron economy. To provide some insight, the partial neutron economy of the actinides in the ^{232}Th and ^{238}U irradiation chains is analyzed in this subchapter.

The neutron economy of the equilibrium cycle is a particular case because all nuclides creation and destruction rates are in balance, and all actinides concentrations are constant. The neutron economy, also referred to as neutron tallying, has usually two pillars. The first one is the neutron generation, which is determined by the average number of neutrons emitted per fission, labelled as $\bar{\nu}$. This number is either related to the main fissile nuclide ^{233}U or ^{239}Pu or can be a weighted average over all fissile nuclides in the core. The second pillar relies on the fact that 1 neutron is needed for sustaining the chain reaction and one for the conservation of synthetic actinides concentration. Accordingly, to start with, two neutrons must be subtracted from the balance.

Fig. 9 D-factor of ^{242}Pu for Th-U and U-Pu cycles and 16 selected reactors.

Fig. 10 Neutron absorption rate for 10^9 atoms of ^{242}Pu for Th-U and U-Pu cycles and 16 selected reactors.

η -2

The most traditional measure of the neutron economy is the η factor of the main fissile nuclide, i.e., of ^{233}U and ^{239}Pu . It is a product of $\bar{\nu}$ of the main fissile nuclide and its fission probability. The respective η -2 provides reasonable first estimate of the neutron excess. It is oriented on the conservation of the main fissile nuclide concentration. It assumes the need of two neutrons: one to be absorbed on the main fissile nuclide itself and other on the main fertile nuclide. Since η includes the fission probability it already accounts for the neutron capture by the main fissile nuclide. However, it is only approximate neutron tallying. Only main fissile and fertile nuclides and only selected reactions are considered. The impact of other nuclides and reactions in the irradiation chain is neglected. The accuracy of this estimate can be improved by:

1. Accounting for the relative share of fast Fission $F_{232\text{Th}}$ or $F_{238\text{U}}$ of the main fertile nuclide.
2. Accounting for the other synthetic actinides contributions to the neutron balance. This impact can be at best expressed by the D-factor of the respective ^{234}U and ^{240}Pu nuclides multiplied by the main fissile nuclide capture rate.
3. Accounting for the bypass of the main fissile nuclide by ^{233}Pa and ^{239}Np capture rate. Since this capture results in ^{234}U and ^{240}Pu buildup, this term is composed from own ^{233}Pa and ^{239}Np relative capture rate and from the ^{234}U and ^{240}Pu impact on the neutron balance.

The overall neutron balance n_{B1} , for instance for the ^{232}Th can be expressed as:

$$n_{B1} = \eta_{233\text{U}} - 2 + F_{232\text{Th}} - \frac{C_{233\text{U}}}{C_{233\text{U}} + F_{233\text{U}}} D_{234\text{U}} - \left(2 \frac{C_{233\text{Pa}}}{C_{233\text{U}} + F_{233\text{U}}} + \frac{C_{233\text{Pa}}}{C_{233\text{U}} + F_{233\text{U}}} D_{234\text{U}} \right) \quad (4)$$

where F, C, and D represent the fission rate, capture rate and the D-factor. The notation for the ^{238}U irradiation chain will be similar; however, the reaction rates for corresponding nuclides ^{238}U , ^{239}Pu and ^{239}Np should be applied.

Neutrons produced per fission

A very similar method relies on the neutron balance in a self-sustaining breeder, where the average number of neutrons produced per fission is reduced by 2, assuming one neutron for fission and one for breeding. This method was actually applied in form of reactivity break-down in Krepel and Losa (2019). In this case the $\bar{\nu}$ represents weighted average over all fissile nuclides in the core. The $\bar{\nu} - 2$ provides a less precise first estimate, because it completely neglects the actinides parasitic neutron captures. The accuracy of this estimate can be increased by:

1. Accounting for the relative share of fast Fission $F_{232\text{Th}}$ or $F_{238\text{U}}$ of the main fertile nuclide.
2. Subtracting the Capture rate C_{Ac} of all synthetic actinides.
3. Accounting for the (n, 2n) reaction on main fertile nuclide. It should be accounted twice, because it produces an extra neutron and it reduces number of neutrons needed for main fertile transmutation.

The overall neutron balance n_{B2} , for instance for the ^{232}Th can be expressed as:

$$n_{B2} = \bar{\nu} - 2 + F_{232\text{Th}} - \frac{\sum_i C_i}{\sum_i F_i} + 2R_{232\text{Th}}^{(n,2n)} \quad (5)$$

Costs of synthetic actinides fission

Alternative neutron tallying was introduced in Krepel (2021). It relies on $\bar{\nu}$ as a weighted average over all fissile nuclides in the core, knowledge of fission rate distribution between the nuclides in the irradiation chain, and neutron cost for each nuclide creation and fission (see Table 2 in Krepel (2021)). This method is also only approximate, and more accurate values are obtained when:

1. The nucleons lost by α decay reaction are accounted for.

The (n, 2n) reaction is already included in the respective nuclides creation cost from Table 2 in Krepel (2021). The overall neutron balance n_{B3} , for instance for the ^{232}Th can be expressed as:

$$n_{B3} = \bar{\nu} - \sum_i F_i n_i - 4 \sum_i \alpha_i \quad (6)$$

D-factors of ^{232}Th and ^{238}U

The D-factor of the main fertile nuclide represents the number of neutrons that are required for its ultimate transmutation. Hence, the D-factors of ^{232}Th and ^{238}U cover the neutron balance of the whole respective irradiation chains. However, the D-factors are defined as the neutron cost for ultimate transmutation. Hence, if there is a neutrons excess, the D-factors are negative. The equation for neutron balance n_{B4} has thus the trivial form:

$$n_{B4} = -D_{232\text{Th}} \quad (7)$$

Neutron economy overview

The above four neutron tallying method should provide exactly the same neutron balance. However, since not all necessary corrections are applied, the values in Tables 1 and 2 slightly differ. Usually only the main fertile nuclide (n, 2n) reaction is accounted for. Similarly, there are several minor paths through the chain, which are not always properly considered in the neutron tallying. The values averaged over these four methods are plotted in Fig. 11.

The results in Fig. 11, even though they do not account for parasitic neutron absorption by the structural materials, coolants and moderators, illustrate the difficulty to breed in the U-Pu cycle in thermal reactors. The PHWR is the only reactor in this study, which has a slightly positive neutron balance of the actinides chain in the U-Pu cycle. Nonetheless, it is not sufficient for realistic breeding. Fig. 11 also shows that the HPLWR, FHR, and RBMK performance in the U-Pu cycle does not differ dramatically from other thermal reactors and confirms that the very low BG in Fig. 3 is caused by parasitic neutron captures by non-fuel materials.

The values in Tables 1 and 2 can be also used for a general discussion about the U-Pu and Th-U closed cycles. The improved breeding in harder neutron spectra, surprisingly, is not related to the larger average number of neutrons emitted per fission. For each particular nuclide neutron economy relevant parameters are increasing with spectrum hardening. Nonetheless, the equilibrium fuel composition changes and enhances compensating effects. Thus, in the U-Pu cycle there are 2.9 neutrons emitted per fission, while in the Th-U cycle only about 2.5 neutrons. The higher number of available neutrons is the biggest advantage of the U-Pu cycle in terms of neutron economy. Another advantage of the U-Pu cycle is that up to 15% of the fissions are fast fissions of the fertile ^{238}U . Unlike the number of neutrons emitted per fission, the direct fission strongly depends on the spectrum. The strongest disadvantage of the U-Pu cycle is that the ^{239}Pu fission probability steeply decreases down to 60% with spectrum softening, whereas ^{233}U fission probability stays constant around 90%.

The dominance of the U-Pu cycle in all fast reactors ends with the MSFR, which is considered a fast reactor system. However, its spectrum has the same share of fast neutrons as the LWR (Krepel, 2021). In the Th-U cycle many thermal spectrum system have the same performance as MSFR. Unfortunately, it is the parasitic neutron capture by non-fuel materials which deteriorates the balance.

Summary

The nuclear fuel cycle relies on resources, which are not renewable and not every planet in our solar system or in the universe has them. The nuclear fission chain reaction is so far the only known alternative to nuclear fusion for producing energy from nuclear transmutation processes. The self-sustaining breeding in closed cycle is the best option to fully utilize the potential of the primordial actinides ^{232}Th and ^{238}U . The neutron economy of this process is tight, and not all advanced reactors can be operated as self-sustaining breeders. This article tried to explain the reasons for this.

Two methods have been applied for the fuel cycle performance evaluation. The first method relies on D-factors. This method was originally proposed to quantify the transmutation capability of waste burning reactors. Nonetheless, it can be applied also to ^{232}Th and ^{238}U utilization in nuclear fission reactors. The D-factors represent the number of neutrons which are needed to ultimately fission one atom of a given nuclide. Accordingly, knowledge of the equilibrium irradiation chain is needed to quantify them. The second method applied here is the equilibrium method. Similarly, like the D-factors, this method was proposed for waste

Fig. 11 Neutron balance of the ^{232}Th and ^{238}U irradiation chains. Positive numbers represent neutron excess, negative numbers neutron deficit.

burning reactors, which use synthetic actinides as a feed. However, also here if solely ^{232}Th or ^{238}U is used as a feed the resulting equilibrium represents the self-sustaining breeder. It is a characteristic of this method that the equilibrium isobreeding state is achieved also for reactors, which are subcritical in equilibrium and cannot act as a breeder in reality. The equilibrium state should be understood as an Eigen-state of the reactor and the equilibrium fuel composition as the Eigen-vector of the Bateman burnup matrix.

The knowledge of equilibrium parameters was used to assess the breeding ratio, as the foremost fuel cycle performance parameter, in each simulated reactor. The reactors can be classified into four categories based on their equilibrium breeding ratio. The second fuel cycle performance parameter, achievable burnup and its relationship with the breeding ratio, was discussed and the importance of absolute fissile fuel share was stressed. The lower achievable burnup in thermal spectrum reactors is often assigned to the higher FPs microscopic cross-sections. This is, nonetheless, only a minor contributor to the issue in comparison to the impact of the absolute fissile fuel share.

The initial fissile load for the open and closed cycle was addressed together with its relation to the achievable burnup in an open cycle. The means of criticality maintenance were not addressed as such; however possible reactivity variations in different reactors and fuel cycle types were discussed and the interconnection with breeding ratio illustrated. It is obvious that positive initial breeding gain can partly compensate for the neutron economy deterioration by FPs at the end of cycle. The transmutation capability was quantified by D-factors and by the reaction rate per atom. As expected, the transmutation of legacy synthetic actinides costs more neutrons in a thermal reactor. At the same time, the more efficient transmutation process in fast reactors can be slower.

Finally, the neutron economy of the actinides equilibrium composition, or actually of the ^{232}Th and ^{238}U irradiation chains is analyzed using four different neutron tallying methods. They all rely on the fact, that the fuel composition and reaction rates are stabilized in equilibrium. The general conclusion is that: (1) the self-sustaining breeding in closed cycle offers better neutron economy and higher achievable burnup in fast reactors; (2) the U-Pu cycle profits more from spectrum hardening and has better neutron economy, in which more neutrons are generated per fission but also parasitically captured; (3) the Th-U cycle is less sensitive to the spectrum hardening and has better neutron efficiency, in which the lower neutron generation per fission is compensated by lower parasitic captures; (4) breeding in thermal spectrum may result in prohibitively high fuel reprocessing frequency.

One potentially surprising conclusion of this study is that the better breeding in harder spectra is not related to the higher average number of neutrons emitted per fission. Even though, individual neutron yields are increasing with spectrum hardening, the changing fuel composition compensates for this effect. Hence, no matter in which reactor, in the U-Pu cycle there are roughly 2.9 neutrons emitted per fission, while in the Th-U cycle only about 2.5 neutrons are emitted per fission. The higher number of neutrons per fission, together with up to 15% of the fissions of the fertile ^{238}U that are induced by fast neutrons, is the biggest advantage of the U-Pu cycle. Unlike the number of neutrons emitted per fission, the direct fertile fuel fission probability as well as ^{239}Pu fission probability strongly depends on the spectrum. The ^{238}U fission is a threshold reaction, and the fission probability goes to zero below the threshold energy. The ^{239}Pu fission probability decreases steeply down to 60% with spectrum softening, whereas the ^{233}U fission probability stays constant around 90%. The rate of other synthetic actinides creation is thus three times higher for the U-Pu cycle in thermal reactors.

This is the third of a series of three chapters that is dedicated to the identification of the advanced reactor technologies that are capable of self-sustaining breeding when fueled with either ^{232}Th or ^{238}U and to the investigation of properties of the resulting equilibrium fuel cycles. The trivial conclusion of this study is that (1) both primordial nuclides ^{232}Th and ^{238}U can be utilized by self-sustaining breeding in closed cycle; (2) in case of ^{238}U , the B&B mode in an open cycle is also possible; (3) synthetic actinides, until

they are reasonable recoverable, should be considered as resource and catalyzer of the ^{232}Th and ^{238}U utilization; and (4) engineering and technological issues should be overcome and not allowed to discredit this natural resource.

Introduction

The field of modeling and simulation (M&S) is dedicated to devising the mathematical models that best describe a physical phenomenon, implementing them into a computer code, deploying them on suitable computer architectures and applying them to specific problem simulation.

In terms of models, the field of nuclear engineering has experienced a quick progress in its early decades (Ronen, 1986). However, the growing availability of computational resources, together with the decreasing number of available experimental facilities, is increasingly leading the community towards a design-by-simulation paradigm. In turn, the higher fidelity and the reduced uncertainty margins required by this design strategy are gradually transforming the field of M&S. In addition, significant progress is observed in relatively new fields such as multiphysics, and in cross-disciplinary fields like Computational Fluid Dynamics (CFD) and Machine Learning.

In terms of computer codes, M&S of advanced nuclear reactors has been closely related to that of conventional reactors. In the past, tools were mainly developed for the traditional light water reactors (LWRs) that constitute the majority of the Gen I – III reactors (Brown, 2021; Hamon, 2021; Shwageraus, 2021; Stanculescu, 2021), and subsequently adapted to the analysis of reactors relying on other coolants than water, as well as on innovative nuclear fuels and fuel cycles. This approach allows strongly limiting development efforts, as well as verification and validation (V&V). However, the relatively old programming languages and paradigms employed in legacy codes often make their modification time consuming. In addition, code extension often results in tools with only limited capabilities for the analysis of non-LWR systems. Nowadays, progress in the field of Computational Science has made the effort of developing new dedicated codes comparable to that of modifying legacy codes, and the two strategies tend to go hand in hand. The choice has become a trade-off between flexibility and computational performances on one side, and robustness and reliability on the other. It often depends on the availability of in-house legacy codes, on the type of expertise of the developing team, on the importance of high-performance computing (HPC) in the target reactor technology, on the target reactor technology itself, and on the scope of the work (research or licensing).

This chapter focuses on models and codes employed for nuclear reactor design and for the analysis of its steady-state, operational transients and design-basis accidents.¹ No explicit discussion is provided about models for probabilistic risk assessment (Modarres and Kim, 2021), fuel-coolant interaction, core melting, containment analysis, integrity, release of radionuclides (Singh, 2021), transport of radio-nuclides in the atmosphere, radiation protection (Pevey, 2021), specific material performance, etc. Such extended scope would vastly transcend the space allotted to this Chapter. Additional relevant information is provided by Martin (2021), and Kirkland (2021).

Models and algorithms

M&S of nuclear reactors is a multidisciplinary field that requires the investigation of several different and interrelated phenomena. Many phenomena, such as neutron transport, fuel cycle, and fuel behavior, are specific to nuclear reactor analysis. In other cases, cross-disciplinary M&S methodologies are employed, sometimes tailored to the needs of the nuclear sector.

Neutron transport

The objective of neutron transport studies is most often to predict the spatial distribution and temporal evolution of fission power in a reactor core. Other typical applications are the evaluation of irradiation damage in structural materials, neutron shielding and neutron noise analyses.

The transport of neutrons and their interaction with matter is governed by the Boltzmann transport equation (Stacey, 2007). It can be modeled with minimal approximations by using Monte Carlo methods, i.e., by simulating a large number of random neutron histories (Stacey, 2007). The complex energy and angular dependences associated with the interaction of neutrons with matter challenge instead the use of deterministic methodologies. Several approximations have been proposed in the past to tackle this problem. A first important approximation applies to neutron energy and consists in subdividing the energy spectrum in one or multiple groups, each one with its own average energy and effective cross-sections (multi-group approach). A second approximation is then necessary to treat the angular dependence of the neutron flux and of its interaction with matter. In the method of discrete ordinates, neutrons are subdivided in a certain number of groups based on their direction. In the method of spherical harmonics, the neutron flux is instead expanded in a series of anisotropic functions (the spherical harmonics). A limiting case for spherical harmonics consists in assuming an isotropic neutron flux, which results in the diffusion approximation. In the method of characteristics, the multi-group transport equations are written in terms of linear characteristics curves, traditionally in two dimensions (2-D). Finally, the collision probability method, which is mainly employed for the generation of effective cross-sections, builds an algebraic matrix by evaluating the probability for a neutron born (isotropically) in any of the regions of the core lattice to undergo its first collision in another region.

All these methods have been successfully applied to both traditional and advanced nuclear reactors. Neutron diffusion remains the workhorse for the nuclear community, especially for transient analyses. It provides reasonable approximations for most reactor concepts, with very limited computational requirements. However, the availability of large computational resources is driving the research efforts towards the use of more complex models. For instance, new codes are being developed for the 3-D application of the

¹A postulated accident that a nuclear facility must be designed and built to withstand without loss to the systems, structures, and components necessary to ensure public health and safety.

method of characteristics (Tada et al., 2011; Kouchunas et al., 2015), and significant efforts are being spent towards more efficient and scalable algorithms for discrete ordinate equations (Ragusa and Wang, 2010).

Relevant advances are observed in the field of Monte Carlo analysis, whose intrinsic parallel scalability allow fully benefiting from large HPC facilities. Mainly employed in the past for criticality and shielding calculations, Monte Carlo methods are gradually becoming: an important tool for the generation of multi-group cross-sections; a viable tool for analyzing short transients, such as super-prompt-critical power excursions, with ongoing efforts aimed at modeling delayed neutron precursors in longer transients; and a powerful tool for sensitivity analyses, also thanks to the development of a dedicated perturbation theory (Aufiero et al., 2015a). Finally, while Monte Carlo codes have been historically based on combinatorial geometries, methodologies have been developed to allow employing general unstructured meshes (Leppänen and Aufiero, 2014).

Beside the evident trend towards computationally expensive solutions, new methods have also been developed for specific applications. A good example is that of Molten Salt Reactors (MSRs) (Křepel and Kramer, 2021; Ignatiev, 2021), whose liquid fuel requires modeling the transport of the delayed neutron precursors. To this purpose, many legacy codes have been modified (Křepel et al., 2007), and new codes created (Aufiero et al., 2014a), that include a transport term in the precursor equations. Dedicated methods have also been developed for Monte Carlo codes to be able to evaluate the kinetics parameters with moving precursors (Aufiero et al., 2014b). Another example of development of reactor-specific methodologies relates the modeling of the neutronic impact of core deformations in fast reactors. While traditionally this effect was modeled by parametrizing the cross-sections, and in some cases by uniform radial and axial expansions of the core, modern moving mesh algorithms are currently being developed to allow for a detailed modeling of deformations (see Section “Sodium fast reactors” of this chapter). Another approach to the problem is based on a fixed mesh, but with perturbed equations (Jing and Yang, 2019).

Fuel cycle analysis

Methods for fuel cycle calculations can be subdivided into two main categories. Burnup methods aim at predicting the isotopic composition of the nuclear fuel during irradiation. Based on these results, a second category of methods aims at predicting the evolution of nuclear materials in a reactor fleet, possibly optimizing the deployment of the fleet based on some constraints and figures of merit.

The Bateman equations (Cacuci, 2010) describe the evolution of isotopes in a nuclear reactor. Burnup calculations are based on the assumption that nuclide concentrations can be assumed as constant when solving for the neutron density distribution, and vice versa. As a result, neutron transport and Bateman equations are solved sequentially and iteratively. One has to perform time-independent neutron transport calculations to obtain the various average isotopic production and removal rates, depending on the fuel batch and position in the core. Based on these reaction rates, one can construct and solve the Bateman equations (burnup step). This iterative strategy can be refined by means of predictor–corrector methods for improving the evaluation of the constant reaction rates employed during the burnup step (Yamamoto et al., 2009; Josey et al., 2017).

Unfortunately, the presence of isotopes with very different production and removal rates tends to make the system of Bateman equations extremely stiff, which rules out the use of common methods for ordinary differential equations. The method of matrix exponential is then commonly employed, with several different approximations. A traditional one involves simplifying the Bateman equations by excluding the shortest-lived isotopes, and solving the resulting matrix exponential by using a truncated Taylor series. More recently, the Chebyshev rational approximation method has been demonstrated to work well for large burnup problems while relaxing the need for decay chain simplifications (Pusa and Leppänen, 2013).

A specific case for burnup calculations is that of MSRs. On the one hand, thanks to the liquid fuel, average fluxes and cross-sections do not need to be calculated in several different regions. On the other hand, MSRs often feature complex on-line refueling and/or reprocessing. To simulate this, one needs to modify the Bateman equations to include fictitious production/removal decay constants (Nuttin et al., 2005). Another option is that of employing traditional codes for fuel cycle analysis, but modifying fuel compositions at each burnup step (Powers et al., 2013).

Fuel cycle analyses of pebble-bed reactors (Reitsma, 2021) is another domain that has experienced significant recent advances. The double heterogeneity of the fuel (particles in a pebble, and pebbles in the core) requires special treatments for cross-section generation when employing deterministic methodologies (Rütten et al., 2012). In addition, the flow of the pebbles requires a modified burnup routine. Traditionally this was modeled by radially subdividing the core into “channels,” and the channels into axial zones with different batches of pebbles moving from one axial zone to the next. In recent years, cross-section generation is more often performed by directly applying Monte Carlo methods based on the Woodcock delta-tracking method and employing a stochastic treatment for double heterogeneities, with discrete-element methods for the generation of realistic pebble beds (Rintala et al., 2015).

Fuel behavior

Fuel behavior analyses have two main objectives: investigating the fuel performance at nominal conditions during its residence time in a reactor; and, starting from a certain fuel state, predicting the behavior of the fuel during operational and accidental transients. Although separate codes have often been developed in the past for these two types of analyses, there is a recent tendency to develop tools that are suited for both (Van Uffelen et al., 2018).

Fuel behavior investigations require simulating: temperatures, strains and stresses in fuel and cladding; gap conductance; the thermo-mechanical contact between fuel and cladding; the evolution of major isotopes in the fuel; the generation and release of fission gases; the chemical interaction among fuel, fission products, cladding and coolant; and a myriad of specific phenomena like thermal and irradiation creep, fuel swelling, fuel densification, cladding axial growth, cracking, relocation, formation of high-burnup structures, etc.

Historically, fuel behavior analysis has been performed by following a so-called 1.5-D approach (Van Uffelen et al., 2018). According to this approach, the fuel is subdivided into axial sections, each one featuring a 1-D radial discretization for the thermo-mechanical equations. These 1-D sections are then axially coupled in a loose way by means of a common model for the pressure in gap and plena. The reason for these simple models resides only partly in their limited computational requirements. From an engineering perspective, the nuclear fuel is characterized by such a complex phenomenology that reliable experimental correlations acting on simple mathematical models can turn out to be preferable over complex models with limited empirical content. In addition, experimental data are often limited to fuel centerline temperatures and gas pressures, thus not providing a calibration and validation base for multi-dimensional codes.

Legacy 1.5-D tools have often been developed for LWR analysis. However, the computational framework is applicable to general pin-based nuclear reactors and several legacy codes have then been extended to advanced reactor systems. A major challenge remains in the development of the related experimental correlations and models.

In addition to 1.5-D tools, some efforts have been spent in the past towards simple 2-D models (Rashid et al., 2014). More recently, the growing computational resources are pushing for the development of multi-dimensional codes (Sercombe et al., 2009; Williamson et al., 2012; Soba and Denis, 2015; Scolaro et al., 2020). An objective is to complement legacy codes for the analysis of non-symmetric cases (viz. missing pellet surface, or non-symmetric power/cooling, notably in boiling water reactors). The multi-dimensional capabilities also allow for more mechanistic simulations, which in turn provide scientists with a better understanding of the various phenomena at play.

Multi-dimensional codes tend to relax the need for experimental correlations, thus facilitating their application to unconventional fuels and advanced reactors. In this sense, some of the recent multi-dimensional codes (Williamson et al., 2012; Scolaro et al., 2020) have been based on general libraries for the solution of partial differential equations, which allows for an easier adaptation to non-traditional fuels like the TRISO-based ones (Hales et al., 2013; Helmreich, 2021).

Thermal-hydraulics and system behavior

The thermal-hydraulic analysis of a reactor is a challenging task (Todreas and Kazimi, 2001; Kirkland, 2021). The geometrical complexity of a reactor core often forces to employ significant simplifications, which combines with the well-known difficulties in modeling turbulence and, for certain reactors, two-phase flows. Different methods can be used depending on the level of detail required by the simulation and on its objective.

System codes

By system code one normally means a primarily one-dimensional (1-D) thermal-hydraulic code capable of modeling the entire reactor system, including primary, intermediate and secondary loops. These codes are normally based on 1-D finite volume (FV) or finite difference discretizations of the Navier-Stokes equations, and/or of the Euler-Euler multiphase flow equations (typically 6 equation models). The reactor core is often modeled using multiple parallel 1-D channels. These codes can be used for both steady-state and transient analysis, including accidental situations. For this reason, they normally include relatively simple models for neutron kinetics and fuel temperatures.

System codes have been among the first tools being developed for nuclear reactor analysis, and they still represent today the workhorse of the community. In particular, the decades-long calibration, verification and validation and the heavy use of experimental correlations makes them the preferred choice for reactor licensing. Recent activities have focused on improving their multi-physics capabilities via inclusion of improved models for fuel (US NRC, 2007), as well as via a coupling with external codes for neutron transport. In addition, simplified three-dimensional (3-D) capabilities have gradually been introduced.

System codes have typically been developed for LWRs, and several activities have been carried out to extend their capabilities, notably for fast reactors (Mikityuk et al., 2010; Kruessmann et al., 2015; Nikitin and Fridman, 2018). More recently, system codes have started to be adapted to MSRs and the movement of delayed neutron precursors (Leandro et al., 2019).

Porous-medium approach

Porous-medium modeling (Todreas and Kazimi, 2001) is a common engineering approach for simulating the flow of a fluid in complex structures. Porous-medium equations can be obtained by volume-averaging the Navier-Stokes and energy equations. This results in: an additional porosity term, indicating that only a fraction of the volume is occupied by the fluid; and additional source terms that describe the interaction of the fluid with the subscale structure (viz., the fuel pins in a reactor core). The porous-medium equations revert to 1-D “system code” equations when restricted to one dimension. In this sense, porous medium models can be considered as a multi-dimensional extension of system codes. As a matter of fact, energy and momentum sources are often modeled based on the same correlations for Darcy friction factors and Nusselt numbers that are used in system codes.

The porous medium approach, in its general form, has experienced a limited success in the nuclear community. However, this approach has the advantage of being applicable to general unstructured meshes, which makes it a suitable option for recent

multiphysics codes based on FV or finite element (FEM) discretizations and standardized mesh treatments. In addition, the porous-medium equations reduce to standard Navier-Stokes equations in clear fluids, when porosity is equal to one and the source terms to zero. This allows for a unified, implicitly coupled treatment of pool (or plena) and core thermal-hydraulics. This possibility is particularly interesting for simulating the setup of a natural circulation regime in sodium fast reactors (SFRs) (Heidet, 2021).

Another field of application for the porous-medium approach is the analysis of pebble-bed reactors. In these reactors, the core structure is essentially isotropic and homogeneous, which makes the porous-medium treatment a natural choice for their thermal-hydraulic analysis.

Sub-channel codes

The sub-channel approach (Moorthi et al., 2018) is a special case of the porous-medium approach where the control volumes are standardized to a specific layout. This approach is normally employed for pin-based nuclear reactors. Radially, sub-channels are typically the size of a single fuel rod and associated coolant. Different sub-channels can be used for different positions in an assembly, as shown in Fig. 1 for the specific case of an SFR assembly. In the case of square pin lattices, either rod-centered or coolant-centered square sub-channels can be employed. The use of standardized and properly selected nodes has several benefits over the use of possibly unstructured control volumes in a general porous-medium approach. For instance, use of a triangular control volume in a hexagonal lattice (Fig. 1) allows employing one single expression for radial momentum and energy exchange between control volumes, while the use of an unstructured mesh and Cartesian coordinates would require at least two different expressions. In addition, one can choose volumes that correspond to physical sub-channels with different properties. Finally, and notably for rod-centered treatments, one can associate the power of each single rod to its own channel, thus fully resolving the heterogeneities inside an assembly. As a drawback, sub-channel codes are often based on dedicated algorithms, instead of standardized treatments for unstructured meshes. This requires a time-consuming set-up of code-specific interfaces when coupling them to other codes.

Computational fluid dynamics - single phase

CFD is a vast domain that extends far beyond nuclear energy. It can in principle be referred to the any computational methodology for fluid flows. Often however, and especially in the nuclear field, CFD refers specifically to fine-mesh multidimensional algorithms for detailed fluid flow analyses. This allows clearly distinguishing it from 1-D system codes and from the porous-medium or sub-channel approaches.

Laminar flows can be solved without relevant approximations for problems of engineering interest. On the other hand, the Direct Numerical Simulation (DNS) of Navier-Stokes equations in turbulent cases requires special numerical treatments and it is extremely requiring from a computational perspective. Two main approximations have been devised to simulate turbulent flows, namely: Reynolds Average Navier-Stokes (RANS) and Large Eddy Simulation (LES). Both approaches aim at filtering out part of the turbulent time and length scales. The RANS approach is based on a time average of the Navier-Stokes equations. The resulting

Fig. 1 Example of sub-channels for a SFR fuel assembly. Different types of sub-channels are marked in *blue*, *green*, and *yellow*. Courtesy of Chirayu Batra, IAEA.

approach has limited computational requirements but also significant shortcomings, for instance in case of flow detachments. In addition, due to the time averaging, the RANS approach is in principle unsuited for unsteady flows. However, a time dependence is often retained for simulating transients that are slow compared to turbulent time scales (viz., average velocity and temperature changes during a loss-of-flow accident). The LES approach is instead based on a spatial filtering of the equations and allows simulating unsteady flows. It normally features a higher accuracy, but at the cost of a much higher computational footprint, often calling for special numerical treatments such as the spectral element method (Fischer et al., 2008).

The available computational resources are making CFD calculations common in the nuclear engineering community. RANS analyses are employed for the analysis of plena and pools (Moreau et al., 2019), spacer grids, fuel assemblies (Roelofs et al., 2019), as well as for standard CFD applications like pipes, pumps, and heat exchangers. RANS is also becoming the reference approach for modeling the fluid flow in fast-spectrum MSRs.

LES analyses are typically aimed at smaller application like T-junctions, cross-flow over obstacles and parallel shear flows (Simoneau et al., 2010). However, some studies for entire fuel assemblies are already being performed on large HPC facilities (Merzari et al., 2017). Other LES applications include the local fluid flow in pebble-bed reactors (Shams et al., 2014) and the salt flow in the core of fast-spectrum MSRs. In the case of MSRs, the use of LES can help identifying potential neutronic effects of fluid flow instabilities, as well as improving predictions on flow detachment and stagnation points. Thanks to the capability to investigate unsteady flows, LES is also a reference choice for fluid-structure interaction studies aimed at predicting local vibrations, such as for the fretting of space grids (Bakosi et al., 2013).

DNS analyses are mainly limited to simple geometries such a single backward facing step. They often aim at creating reference solutions for benchmarking RANS and LES solutions, notably for cases that are specific to the nuclear engineering field. An example is that of low-Prandtl number flows (Oder et al., 2019). Another typical application is the investigation of boundary layers, including for instance the effect of surface roughness (Chatzikyriakou et al., 2015).

Computational fluid dynamics - multiphase

Similar to CFD, multiphase CFD (sometimes referred to as Computational Multi-Fluid Dynamics, or CMFD) is employed in several fields of science and engineering. In nuclear, the application of multiphase CFD is mainly restricted to two-phase flow simulations. There is an impressively large set of available methods (Bestion, 2012; Kharangate and Mudawar, 2017), but one can broadly distinguish between Eulerian and Lagrangian methods, as well as between single- and multi-fluid methods. An additional category is that of lattice Boltzmann methods. These broad methodologies include several sub-methods. For instance, single-fluid Eulerian methods can further be distinguished in the way of tracking and reconstructing the interface between liquid and vapor. Multi-fluid methods can simply model the liquid and vapor fractions, or include multiple “fields” to model continuous and dispersed phases, as well as multiple groups of fields depending e.g., on the size of bubbles. Multiphase CFD method can be further subdivided based on the turbulence treatment: RANS, LES, and DNS. A general classification of Eulerian multiphase CFD models has been proposed in (Bestion et al., 2014) and is reported in Table 1.

There are several possible applications of interest for multiphase CFD in the nuclear field (Bestion et al., 2014). An important example is the prediction of Critical Heat Flux (CHF) for both the Departure from Nucleate Boiling (DNB) and the dryout in LWRs (Yadigaroglu, 2014). Single-fluid and lattice Boltzmann methods are both used to investigate the details of bubble growth and coalescence. Two-fluid models are less computationally expensive and are typically employed for larger-scale predictions at a channel level (Brewster et al., 2019). Some major advances in the field of multiphase CFD are associated to CHF predictions, with activities on the improvement of closure relations for multi-fluid models (Baglietto et al., 2018), as well as for the creation of improved and larger-scale models for single-fluid prediction of local phenomena (Sato and Niceno, 2018).

Multiphysics

Multiphysics refers to the coupled simulation of different physical phenomena. In the field of M&S, different physical phenomena are sometimes referred to as “physics.” A typical example in nuclear engineering is the coupling of neutron transport with core thermal-hydraulics. Multiphysics simulations can be categorized in several ways:

- One- or two-ways coupling. In one-way coupling, it is assumed that one phenomenon impacts the other, but not vice versa. This is for instance the case of zero-power reactors: a change in temperature in the moderator will affect the neutron balance, but the corresponding power variation will not significantly affect the temperature of the moderator. In two-ways coupling instead the two phenomena affect each other, like neutronics and thermal-hydraulics in nuclear power plants.
- Internal or external coupling. In the case of internal coupling, the same code is employed for simulating two different phenomena. This is for instance the case of system codes with built-in models for point kinetics and fuel behavior. In external coupling, two or more existing codes are coupled via an interface. This allows employing existing codes, but with a higher risk of computational bottlenecks. The coupling interface can be part of one of the two codes, or an additional independent code. It can operate at the level of the computer RAM, or of the hard disk (for instance by creating and exchanging text files).
- Explicit or implicit coupling. In explicit coupling, one single and separate calculation (or one per time step) is performed for the single-physics models. It is suitable for one-way couplings, or for transient simulations with very small time steps. In case of implicit coupling, models are instead solved so that the interdependence of the coupling variables is fully resolved (at each time step, in case of time-dependent simulations). Implicit coupling can be obtained by iteration, or by directly constructing and solving a block coupled linear matrix. It should be preferred over explicit coupling in two-ways couplings.

System codes often allow for two-ways, internal, implicit couplings of thermal-hydraulics, neutronics and fuel behavior ([US NRC, 2007](#)). However, these neutronic and fuel behavior models are often highly simplified and significant efforts have been dedicated in the past to the coupling of system codes with models for spatial neutron kinetics ([US NRC, 2020](#)). In general, coupling of legacy codes has represented the most common methodology to achieve multiphysics simulations. It allows employing validated, reliable codes while limiting potential sources of errors to fairly simple interfaces. Today, it represents the reference methodology for the safety analysis of LWRs ([Chauliac et al., 2011](#); [Michal and Kothe, 2011](#); [Valtavirta, 2018](#)). It is also employed sometimes for first-of-a-kind implementations of novel methodologies, such as the coupling of Monte Carlo codes with finite-volumes codes ([Aufiero et al., 2015b](#)), sub-channel codes ([Ferraro et al., 2019](#)), and fuel behavior codes ([Valtavirta et al., 2017](#)).

However, external code coupling has some disadvantages: it is prone to computational bottlenecks; it makes it difficult to implement advanced coupling methodologies such as high-order time integration, sub-stepping, block-coupled matrix solution, etc.; and it limits the overall computational performance to that of the least-performing single-physics code. For these reasons, the last decade has witnessed a flourishing of activities dedicated to the development ab initio of new numerical platforms for the multi-physics analysis of nuclear reactors ([Gaston et al., 2009](#); [Clifford, 2013](#); [Fiorina et al., 2015](#)). Considered prohibitive in the past, the development of new codes is nowadays streamlined by some important advances in the field of Computational Science. Modern programming languages (e.g., C++, Python, Java) and paradigms (viz., object-oriented programming) allows for a quick implementation and an effective structuring of very large codes, while strongly limiting maintenance and simplifying code modification. In addition, the availability of modern numerical libraries (e.g., OpenFOAM, PETC, libMesh) allows focusing on high-level equations and algorithms, while employing available routines for discretization, matrix solution, mesh-to-mesh projection, mesh deformation, mesh search, etc. This approach carries with itself the complimentary benefit of employing highly optimized, massively-parallel, and verified routines for the most complex and computationally requiring parts of a code (viz., mesh management, discretization, matrix solution).

Transversal trends

Some important trends are observed throughout the different modeling domains, namely: the development of codes that can exploit the potential of HPC; the development of surrogate models; the increasing use of machine learning and data science methodologies; and the growing role of open-source software.

The growing computational resources have been driving significant research activities aimed at improving the parallel scalability of legacy codes, as well as at writing new codes aimed at exploiting the full potential of HPC. When writing new codes, a clear tendency is observed to make use of available numerical libraries for scientific computing, with an increasing use of methodologies based on FEM and FV discretizations on unstructured meshes. A recent challenge when developing tools for HPC applications is the growing use of vector and graphical processing units. To exploit these hardware components, numerical algorithms should be developed to allow for vectorization, i.e., for performing the same operation simultaneously on a certain number of processing units. However, many algorithms employed in the nuclear field are not suitable for this kind of computation. Typical examples are history-based transport algorithm for Monte Carlo codes, as well as common matrix preconditioners and solvers used in FEM and FV methods.

Despite the growing computational resources, the intrinsic limits of the integrated circuit transistor technology are expected to gradually lead to higher costs for increasing computing power. For this reason, the nuclear engineering community is also looking at developing light-weight (surrogate) models that could be used for the several calculations required e.g., for reactor design, sensitivity analyses, uncertainty quantification, data assimilation, etc. Different from the past, where faster models were mainly obtained via

simplifications in the physics of the problem, the community is now increasingly looking at reducing the computational footprint by applying general mathematical models. An example is the use of projection-based reduced order models (Lorenzi, 2019), that have experienced a good success in the CFD community and that are currently becoming popular e.g., in neutronics, fuel behavior and multiphysics. Another notable example is the use of machine learning techniques, most typically deep artificial neural networks.

In general, data science and machine learning methodologies are gaining increasing attention. Main reasons for this are: the impressively fast progress that these fields are experiencing; their accessibility in terms of theoretical background; and the availability of several user-friendly libraries and tools that allow inexperienced users to quickly develop relatively sound and efficient models. Fields of applications include surrogate models, regression models for physical and chemical properties, closure relationships, fault detection and forecast.

Another important trend in the field of nuclear science and technology is that towards open-source software. Following successful examples e.g., in the fields of CFD (OpenFOAM, 2020) and machine learning (Sonnenburg et al., 2007), open-source and collaborative software development are increasingly perceived as a way to accelerate innovation by enlarging the bandwidth for productivity, limiting work duplication, and multiplying V&V efforts (Fiorina et al., 2020).

Examples of applications

The methods discussed in the previous section are routinely used for the analysis of existing reactor systems. Two types of advanced reactors are presented in this section as boundary cases to illustrate how different methods and approaches can be employed for specific applications. In particular, SFRs represent a reactor type with a relatively traditional design and a very high technology readiness level. MSRs on the other hand are a good example of a non-traditional reactor concept that challenges the use of standard methodologies and codes.

Sodium fast reactors

SFRs are arguably the advanced reactor technology that is closer to large scale commercial exploitation. Several methodologies and codes have been developed in the past by various institutions worldwide for investigating their steady-state and transient behavior. Recent efforts have been focused on both the advanced coupling of legacy codes and on the development of new platforms. In addition, new tools have been developed for a higher-fidelity investigation of some safety relevant phenomena.

Two examples of advanced code systems based on legacy codes are the FAST code system (Mikityuk et al., 2010) employed at the Paul Scherrer Institut (Switzerland), and the MATHYS code (Gerschenfeld et al., 2017) developed at the CEA (France). The FAST code system results from the integration and coupling of several state-of-the-art codes, as shown in Fig. 2. It includes the ERANOS code system for static neutronics calculations (Doriath et al., 1993), as well as a coupling of TRACE, PARCS and FRED (Joo et al., 1998; US NRC, 2007; Mikityuk and Fomitchenko, 2000) for neutron kinetics, thermal hydraulic, and fuel transient analysis, respectively. Besides coupling and interfacing a full set of codes for fast reactor analysis, many of these codes have been extended or modified. As an example, the EQL3D procedure (Křepel et al., 2009) has been developed on top of the ERANOS code for 3-D equilibrium fuel cycle calculations, while the TRACE code has been extended to two-phase sodium flow (Chenu, 2011). The FAST code system has been successfully employed for the analysis of several SFR design, including Phenix, Superphenix, ASTRID and the European Sodium Fast Reactor.

The MATHYS code is an example of integration of thermal-hydraulics codes aimed at an improved simulation of the SFR primary pool in specific scenarios. An example of such a scenario is the passive decay heat removal by natural circulation, where complex natural convection patterns set up that include thermal stratification in the pool and inverse flow in the inter-assembly gaps. To properly model the interaction between the flow in the assemblies, in the inter-assembly gaps and in the pools, the MATHYS code couples the CATHARE system code, the TrioMC sub-channel code, and the TrioCFD code for RANS-based CFD. In particular, TrioMC and TrioCFD are coupled through their boundaries, while both codes are coupled with CATHARE by domain overlapping. In typical applications, the overall dynamics of the system is handled by CATHARE, with TrioMC that is used for a detailed modeling of the assemblies, and TrioCFD that is used for detailed simulations of part of the pool (e.g., the outlet jets of core and heat exchangers) and/or of the flow in the inter-assembly gaps.

Beside its integration in MATHYS, the TrioMC code has also been provided with a new scheme for general polyhedral meshes (Gerschenfeld et al., 2019). This extension allows employing it as a CFD code, which in turns allow for a coupled simulation of assemblies, inter-assembly gaps, and pools without the need of an external coupling with TrioCFD. Fig. 3 shows an example of such simulation for an SFR: in the same simulation, a sub-channel approach on a structured mesh is employed for the core while standard CFD on an unstructured mesh is employed for the pools. Similar efforts have also been carried out for adapting CFD codes to porous-medium or sub-channel simulations to obtain unified coarse/fine mesh treatments (Fiorina et al., 2015).

Another field of development in the analysis of SFRs is related to the simulation of reactivity variations associated with core deformations. Prediction of these effects is traditionally obtained by assuming a uniform radial and axial expansion of the core based on average diagrid and fuel temperature, respectively. Multi-group cross-sections are then parametrized based on the average expansion of fuel and diagrid. An example of this state-of-the-art treatment of reactivity effects is the above-mentioned FAST code system. Recent research activities have tried to step beyond this approach by employing thermo-mechanical solvers, and by using

Fig. 2 FAST code system flowchart (Mikityuk et al., 2010).

Fig. 3 Mixed sub-channel/CFD simulation of a SFR obtained using TrioMC (Gerschenfeld et al., 2019).

the resulting deformation field to modify the geometry and mesh in a neutronic solver. A development effort in this sense has been carried out based on the SHARP toolkit, which allows to couple advanced codes for thermal-hydraulics, neutronics and thermal-mechanics. It has been used to achieve a detailed simulation of expansion reactivity effects in a SFR mini-core (Merzari et al.,

2015). A similar work has been performed by using a modern numerical library for PDE solution as a means to develop a single code that includes both neutronic and thermo-mechanical capabilities (Fiorina et al., 2015, 2019). The code has been used to predict core flowering, and a hypothetical core compaction, in the European Sodium Fast Reactor (Fig. 4).

Molten salt reactors

Liquid-fuel MSRs present several modeling challenges, including the continuous salt mixing, the possibility of online reprocessing and refueling, the internal heat generation in the fluid, and the transport of the delayed neutron precursors.

The continuous salt mixing and the online reprocessing/refueling require special tools for fuel cycle analysis. An advanced example of such tools has been presented in (Aufiero et al., 2013) and was obtained by modifying the well-known Serpent 2 Monte Carlo code (Leppänen, 2007). The use of a Monte Carlo code is favored in MSRs by the continuous mixing of the fuel salt, which allows using one single set of reaction rates, without the need of deriving multiple sets for different axial and radial zones. To allow for the continuous fuel reprocessing and refueling, the burnup routine in Serpent 2 has been modified for the use of fictitious decay constants. In addition, a reactivity control mechanism has been included by adjusting the fissile-to-fertile ratio in the feed material. The modified Serpent 2 code has been employed in (Aufiero et al., 2013) for a complete characterization of the fuel cycle characteristics of the Molten Salt Fast Reactor, including equilibrium fuel cycle isotopics, transition to equilibrium, breeding ratios, reprocessing rates, decay heat, radio-toxicities, and irradiation damage in structural materials.

The internal heat generation in the liquid fuel requires instead special treatments for thermal-hydraulics calculations. New correlations have been developed for the prediction of Nusselt number correlations (Di Marcello et al., 2010; Fiorina et al., 2014), showing a significant impact of the internal heat generation, notably for low salt velocities and large channel diameters. In these studies, the interesting possibility has also been pointed out of a negative Nusselt number. Similar to Nusselt number correlations, modified thermal wall functions² have been developed for RANS-based CFD calculations (Fiorina, 2019). Also in this case, the impact of the internal heat source has been shown to be significant. Fig. 5 shows the effect of a modified wall function on the temperature profile in a channel of the Molten Salt Breeder Reactor (Robertson, 1971), and the resulting impact on the reactor behavior in case of a loss of flow transient. In Fig. 5 (left), it can be noted that salt temperatures tend to grow towards the periphery of the channel. To understand this trend, one should keep in mind that in MSRs a fraction of the power is released in the graphite by gammas and fast neutrons, and that this power is evacuated towards the salt. The temperature gradient is accentuated by the internal heat generation, due to the lower salt velocity close to walls. It is the latter effect that is normally neglected in traditional wall functions and Nusselt number correlations, resulting in an underestimation of the wall temperature jump.

Another research area of the MSR community has been the development of tools for the reactor transient behavior. In MSRs, the drift of the delayed neutron precursors creates a very strong coupling between thermal-hydraulics and neutronics. In addition, fast-spectrum MSRs cannot be analyzed using simplified 1-D or coarse-mesh thermal-hydraulic treatments, but require CFD analyses to properly simulate the flow field, the possible detachment of the flow at the core wall, and the possible set-up of recirculation and stagnation zones. In view of these characteristics, the analysis of MSRs has represented a formidable playground for the

Fig. 4 Core flowering (left) and core compaction (right) for the European Sodium Fast Reactor (deformation is magnified).

²A wall function, or law of the wall, describes the velocity of a fluid in the vicinity of a wall and in case of turbulent flows. Similarly, a thermal wall function is employed to evaluate the temperature in the same region and conditions. Wall functions represent the boundary conditions that are most commonly used to represent walls in turbulent flow simulations. They determine the difference in velocity and temperature between a boundary and the first node or cell in the computational domain. Their use allows avoiding extremely refined meshes and it replaces the turbulence models in a region where their validity is not guaranteed.

Fig. 5 Fuel salt temperature in a channel of the Molten Salt Breeder Reactor (left) and corresponding transient behavior in case of a loss of flow (right). Hi-Re indicates high-Reynolds k - ϵ models, while Low-Re indicates a low-Reynolds k - ϵ model that does not require the use of wall functions. The temperature in the left figure is rescaled to the temperature at the channel centerline (Radius = 0).

Fig. 6 Temperature (top-left), velocity and power density (bottom-left), and response to a super-prompt critical reactivity insertion (right) in the MSFR (Aufiero et al., 2014a; Cervi et al., 2019b).

development of new methodologies and codes. As a noteworthy example of these activities, work has performed aimed at the use of OpenFOAM for a complete multi-physics code for the transient analysis of MSRs (Aufiero et al., 2014a; Cervi et al., 2019a,b). The code implicitly couples a RANS-based CFD treatment for thermal-hydraulics with diffusion and SP³ models for neutron transport. It also includes a model for simulating helium bubbling and the corresponding compressibility. An example of the results of this code is reported in Fig. 6.

Acknowledgments

Introduction

Additive manufacturing, which is also known as 3D printing, is a method for manufacturing parts that is often automated. Additive manufacturing creates a part layer by layer based on the specifications provided in a three-dimensional (3D) digital model (ISO/ASTM52900-15, 2015). Conversely, subtractive manufacturing is the removal of material from a bulk solid to create a part. When compared to traditional manufacturing processes, additive manufacturing technologies boast reduced product development times, integrated design and manufacturing efforts, and the ability to create complex geometries once unattainable using traditional fabrication approaches (Babu and Goodridge, 2015). For these reasons, additive manufacturing is being implemented in many

industries, including the automotive (Leal et al., 2017), aerospace (Lyons, 2014; Shapiro et al., 2016), and biomedical (Gunbay et al., 2019; Murr et al., 2010) fields. In many applications, additive manufacturing technologies are cited for their ability to provide rapid prototyping and a time-compressed design feedback loop (Jared et al., 2017; Thompson et al., 2016).

Within the nuclear industry, additive manufacturing is being applied to manufacture obsolete replacement parts for operating light-water reactors (Thomas, 2016c), for subcomponents on light-water reactor fuel assemblies (Thomas, 2017), and manufacturing small numbers of experimental and replacement components for operating research reactors (Hehr et al., 2017). Additional research and development areas of opportunity include leveraging instrumented data-rich manufacturing processes for component qualification, realizing complex geometries for increased reactor performance, and embedding instrumentation to monitor components or to enhance reactor performance characterization (Tobin et al., 2018). Advanced reactor developers are applying additive manufacturing technologies to create complex geometries, and to fabricate materials or mixtures of materials that are not fabricable through traditional means (Betzler et al., 2020d). In particular, microreactor and space reactor concepts have stringent size, temperature, and power density requirements (Nuclear Energy Institute, 2019) for which rapid prototyping, complex geometries, and improved fabrication processes can yield distinct benefits (Miller et al., 2018; Sterbentz et al., 2017).

Nuclear reactor design and engineering is a multidisciplinary, highly regulated industry, not unlike the biomedical and aerospace industries, which are seeing many successful applications of additive manufacturing technologies. In the aerospace industry, additive manufacturing is being used to create flight-critical components (ASM International, 2020). Additively manufactured components first entered nuclear reactor service in 2017 (Ford, 2017), and reactor core components are being employed for the first time in a reactor entering service in 2020 (Day, 2020a). Increased adoption of these technologies over the next decade is expected, but the extent in which they will be adopted are yet to be defined (Thomas, 2016a).

This article provides an overview of the current state of knowledge on additive manufacturing technology applications in nuclear reactor engineering, including:

- Applicable additive manufacturing methods and technologies, including materials, limitations, and fundamental guidelines for design
- Applications for nuclear reactors, including the manufacture of existing component designs for operating reactors and applications to advanced reactors
- Agile reactor design for rapid prototyping and testing akin to early nuclear reactor engineering reactor demonstrations, including analysis of how agile design can yield the most value from applications to advanced reactor concepts
- Modeling and simulation of complex geometries in reactor physics, thermofluidics, and thermomechanical tools, including applications of topology optimization
- The future role of additive manufacturing in the nuclear industry, including potential future application areas
- Discussion of how all of these elements come together for advanced reactor R&D, with a focus on the US Department of Energy (DOE) Office of Nuclear Energy (NE) Transformational Challenge Reactor program (Terrani, 2020), which is exploring many of these concepts in order to accelerate deployment of additive manufacturing technologies in the nuclear industry

The following sections discuss these topics, drawing on current research efforts and the ongoing developments in advanced manufacturing technologies. Due to the rapid advancement in additive technologies, the focus here is on providing general design guidelines instead of a review of specific technologies.

Additive manufacturing

To accommodate the thin fuel claddings, large pressure vessels, and heat exchange machinery, nuclear reactors employ multiple materials at multiple length scales. As such, most additive manufacturing processes (ISO/ASTM52900-15, 2015) are being pursued for nuclear reactor applications, including binder jetting, powder bed fusion, directed energy deposition, and sheet lamination. The feasibility of a technology for a given component depends on the material, the minimum feature size, the overall geometry, and the component function. This section provides a brief overview of these technologies, along with general design considerations for nuclear reactor applications (Simpson et al., 2019). Outside of prototyping, the polymers typically used in additive manufacturing are not useful in the high-irradiation, high-temperature environments characteristic of nuclear reactors. For parts to perform in these challenging conditions, the following methods are being studied:

- *Binder jetting* selectively binds powder with a solvent-polymer solution to build a low-density part (Fig. 2). Geometric flexibility, feature size, and resulting surface roughness are dependent on the material type and powder size (Fig. 1). Ceramics and metals are possible materials. Follow-on techniques for densification are commonly used to meet performance requirements for the part.
- *Powder bed fusion* melts thin layers of powder to build parts layer by layer. Geometries with complex overhangs require additional support structures that accommodate postmachining (Fig. 2). Feature sizes and roughness depend on material type and powder size. Powder bed fusion is a common method for additive manufacturing with metals. Follow-on techniques for selective machining are typically implemented according to the performance requirements of the part.
- *Directed energy deposition* adds material to a small melt pool that is formed with focused thermal energy to build parts volume by volume (Zhang et al., 2018). Feature size and surface roughness depend on the material feed. Metals are typically used for

Fig. 1 A binder jetted silicon carbide part demonstrating geometric flexibility of the manufacturing method. Credit: Kurt Terrani. Terrani K, Jolly B, Trammell M (2020a) 3D printing of high-purity silicon carbide. *Journal of the American Ceramic Society* 103: 1575–1581.

Fig. 2 A simplified diagram of a powder bed additive manufacturing process. Powder spread in an even layer is then selectively bound together using a laser (powder bed fusion) or a binder (binder jetting). The bound layer is covered by another layer of powder from the movement of the build and feed pistons and the roller. Then, the powder in the next layer is selectively bound and the process is repeated.

directed energy deposition. Follow-on techniques for selective machining are commonly used according to the performance requirements of the part.

- *Sheet lamination* bonds sheets of material together to form a large part. This method is ideal for planar-type geometries with metal foils, and it facilitates embedding compatible materials or objects.

Additive manufacturing technologies offer reduced lead times and cost for high value and low-volume production (Pereira et al., 2019) that are characteristic of the complex and customized parts emerging from advanced nuclear reactor designs. Many applications will selectively deploy additive, subtractive, and traditional methods to manufacture and assemble economically competitive components. Additional technologies can be used to combine manufacturing methods. Multimaterial additive manufacturing combines more than one material within the same machine, with or without the same method. Hybrid manufacturing combines additive and subtractive methods within the same machine to achieve the desired surface finishes (Gibson et al., 2015).

Mechanical and thermophysical properties of additively manufactured materials may meet or exceed those of traditionally manufactured materials, but this is dependent on the material type and manufacturing methods. Testing of steel and SiC for reactor applications show comparable properties, with some differences in steel creep behavior due to a high porosity and fine-grained microstructure (Byun et al., 2020b) and some observable impacts from the anisotropic character of SiC (Byun et al., 2020a).

Because of the layer-by-layer approach for building parts, additive manufacturing processes are potentially data rich. Video and thermal imaging may be used to detect abnormalities during manufacturing. Recording this information generates a very large data set that contains the history of the part as a function of space and time. Correlating specific characteristics within this data set (e.g.,

a temperature history at a given location) to defects or failures in the manufactured part (e.g., from testing) is a component of the qualification process for additively manufactured parts (Babu et al., 2018). This type of problem, with very large space- and time-resolved data sets (e.g., imaging and temperature), is ideal for the deployment of artificial intelligence and machine learning approaches (Scime et al., 2020). This is a significant departure from traditional testing and qualification approaches, which rely on statistics and defined processes (Seifi et al., 2017).

Some general guidelines are applied when considering additive manufacturing technologies for nuclear reactor applications:

- An economically viable application of additive manufacturing will likely involve a part redesign process: simply replacing a conventional manufacturing process with an additive manufacturing process to build an identical part is not guaranteed to add value. Incorporating knowledge of the additive manufacturing process in the design process will likely yield a more optimized part for the process while maintaining performance requirements.
- The material type and material density requirements impact the applicable additive manufacturing technology and material maturity.
- The minimum feature size, tolerance, and overall dimension of the part impact the applicable additive manufacturing technology.
- There is an inverse relationship between deposition rates and dimensional resolution, and very large parts with fine detail could take several weeks of machine time to build.
- If a postprocessing step such as densification or machining is required, then the preprocessed geometry must support this functionality.

Additive manufacturing is rapidly developing, so literature on methods, technologies, and capabilities should be reviewed periodically to understand the state of the art for nuclear reactor applications.

Nuclear reactor applications

Objectives for nuclear industry investments in new manufacturing technologies include recapturing lost manufacturing capabilities (Kinsey and Jessup, 2018), reducing manufacturing costs and timelines (Thomas, 2016b), enhancing component performance, and deploying advanced materials (Müller et al., 2019). These technologies include hot isostatic pressing for small modular reactor pressure vessel manufacturing (Gandy et al., 2018) and advanced ceramic-metallic materials for space reactor applications (Houts et al., 2012). While these efforts do not use additive manufacturing methods, they represent new manufacturing approaches to which additive manufacturing may also be applied. For example, efforts focused on wire additive direct energy deposition have yielded large metal structures (Greer et al., 2019; Sridharan et al., 2018) that are directly applicable to large nuclear reactor structural components such as reactor pressure vessels and piping (Sridharan et al., 2019).

The first additive manufacturing applications for operating nuclear reactors started in auxiliary plant components and has slowly migrated to metallic reactor and core components. Many of these components are traditionally manufacturable and are not safety critical components, as outlined below:

- Siemens used powder bed fusion to replace the obsolete design of a fire protection system pump impeller and installed it in a Slovenian reactor in 2017 (Ford, 2017).
- Oak Ridge National Laboratory used ultrasonic additive manufacturing for aluminum alloy control elements to be used in the High Flux Isotope Reactor to study an alternative to costly, manual-intensive manufacturing processes (Hehr et al., 2017); these elements included embedded absorber materials.
- Westinghouse used powder bed fusion for a steel fuel assembly thimble plugging device to demonstrate the manufacturing, qualification, and regulatory approval process for an additively manufactured part (Cleary et al., 2019) that was installed in a US reactor in 2020 (Day, 2020a).
- Westinghouse used powder bed fusion to create a steel fuel assembly bottom nozzle for optimized debris filtering and pressure drop; this effort included using additively manufactured plastics for prototyping and flow testing (Cleary et al., 2019).
- Korea Electric Power Corporation additively manufactured fuel assembly grid spacers to test the applicability of methods and post machining requirements (Nam et al., 2019).
- Oak Ridge National Laboratory and Kairos Power additively manufactured a molten salt pump impeller (Fig. 3) to leverage the iterative design and economic high-rigor low-quantity production characteristics inherent to additive manufacturing technologies (Bumpus, 2020a; Kairos Power, 2020).
- Oak Ridge National Laboratory, Tennessee Valley Authority, and Framatome additively manufactured fuel assembly brackets to demonstrate the iterative design, manufacturing, and qualification process of a safety-related component with a fully advanced digital manufacturing history (Bumpus, 2020b).

In addition to the examples, there are many efforts to apply additive manufacturing technologies for heat exchangers and turbomachinery that are potentially relevant to the reactor industry.

The success of these applications and the deployment of the resulting additively manufactured components in operating nuclear reactors are critical steps for adopting these manufacturing methods in advanced reactor design and deployment. Under the DOE-NE Transformational Challenge Reactor program (Oak Ridge National Laboratory, 2019), Oak Ridge National Laboratory is actively

Fig. 3 An additively manufactured Kairos Power molten salt pump impeller. Credit: Kairos Power. Bumpus KL (2020a) *As ORNL Builds Novel Reactor*. Nuclear Industry Benefits From Technology.

deploying additive manufacturing technologies to rapidly mature an advanced microreactor design (Betzler et al., 2020d), leveraging the geometric flexibility, iterative design, rapid prototyping, and advanced materials possibilities (e.g., high-purity SiC) that additive manufacturing technologies provide. These advanced reactor development applications more fully leverage the inherent characteristics of additive manufacturing technologies by incorporating them within the design process (Betzler et al., 2019, 2020c).

Agile reactor design with additive manufacturing

The term *agile* refers to software development practices that emphasize iterative design, response to change, customer collaboration, and delivery of working software (Shore et al., 2008). These beneficial agile practices are adopted in manufacturing and other technical fields (Nagel and Dove, 1991). Additive manufacturing technologies uniquely enable a rapid iterative design cycle (Fig. 4) that facilitates application of these practices and the realization of their benefits. Agile design characteristics are not typical attributes of the nuclear reactor industry, but these design practices are well suited for advanced nuclear reactor developers working within a more open design space and continuously responding to changing design requirements and rapid technological advances (Day, 2020b).

Agile processes are characterized by four core values (Beck et al., 2001a) and 12 principles (Beck et al., 2001b) as defined for agile software development. The four core values presented below emphasize certain values over others, and they naturally fit within an advanced nuclear reactor design process. In this context, working software applications are equivalent to working prototypes.

Fig. 4 Iterative nuclear reactor design loop with additive manufacturing.

Interdisciplinary collaboration

Individuals and interactions over processes and tools

Nuclear reactor additive manufacturing applications naturally encourage collaboration between mechanical and material engineers familiar with the manufacturing processes and nuclear engineers familiar with nuclear reactor physics, thermal hydraulics, and safety. These collaborations inform the nuclear design process regarding the geometric flexibility of additive manufacturing processes, as well as manufacturing and material constraints, properties, and tolerances. This requires individual engineers to establish the technical constraints and tolerances within their respective areas of discipline.

The resulting informed design approach immediately considers manufacturability and material compatibility before significant design progress or optimization in any specific concentration (e.g., reactor physics or thermal hydraulics). Feasibility in manufacturing is demonstrated as the design progresses. This differs from more traditional nuclear reactor design activities that either do not consider manufacturability or avoid deviating from existing designs to ensure manufacturability.

Working prototypes

Working software over comprehensive documentation

Within this interdisciplinary collaboration, additive manufacturing is critical for rapidly developing and delivering working prototypes. This provides for manufacturing-informed decision-making, and it reduces the risk associated with proposing new designs. This rapid prototyping enables the adoption of a *fail fast* philosophy that preferentially evaluates designs through extensive testing and incremental development. The follow-on learning within this philosophy becomes a necessary and essential part of the agile design process. The longer lead times required by traditional manufacturing approaches would not typically allow this type of expedited design feedback.

Consistently developing working prototypes tests the manufacturing processes and provides design feedback in quantitative and qualitative ways. Exercising the manufacturing process quickly determines geometric characteristics and constraints such as minimum thicknesses, surface roughness, and tolerances. Advanced characterization techniques provide even more information regarding material properties, impurities, and as-assembled geometries. The in-person examination of physical prototypes with a multidisciplinary team is conducive to identifying issues and considering design changes. When this design approach is implemented, the final design is immediately manufacturable if the prototypes were sufficiently characteristic of the final design.

Customer communication

Customer collaboration over contract negotiation

Throughout this design process, reactor physics, thermal hydraulic, thermomechanical, safety analyses, and manufacturing generate refined technical constraints that lead to design changes. This is particularly true for advanced reactor development, which typically has more open design space than traditional incremental nuclear design processes. Technical information is rapidly harnessed from this interdisciplinary, rapid prototyping design process; this information may be used to inform and involve the customer in the decision making process. Additively manufactured prototype processes are particularly effective for communicating technical information, design constraints, and overall progress to obtain customer feedback.

Changing requirements

Responding to change over following a plan

Flexibility and responsiveness to changing requirements is particularly useful for advanced reactor developers who are working in more open design spaces and are responding to consistently evolving technical requirements and new developing technologies. The iterative design process inherent to additive manufacturing applications directly provides the mechanism to respond to a different or new design requirement: as each design iteration ends with a working prototype, the requirements are reviewed and updated, allowing for increasingly refined design requirements through each iteration. With close customer collaboration, these requirement changes are made according to customer feedback. The inherent capabilities of additive manufacturing for rapid prototyping and iterative design provide for the adoption of these agile design characteristics. While the agile design methodology is not necessarily better than a traditional design approach, it is more responsive to changing design requirements and more flexible when incorporating developing technological advancements. For these reasons, it is well suited for advanced reactor development, in which the design space is more flexible, and the requirements are more negotiable. In order to emerge effectively from this agile

design process to deliver a final design, a change in the design approach is necessary to fit the qualification requirements of a final nuclear core design while maintaining technical rigor.

Computational analyses of additively manufactured geometries

The major modeling and simulation components for nuclear reactor design include reactor physics, thermal hydraulics, system dynamics, and thermomechanical analysis, including fuel performance. During steady-state operation, the core design problem is a coupled reactor physics–thermal hydraulics problem: fission heat generated within the fuel is transferred to the coolant and out of the core. Thermomechanical tools predict material behavior and stresses under relevant conditions. System dynamics tools quantify peak temperatures and heating rates during transient scenarios. Reactor physics methods predict core operational and safety characteristics as conditions change during irradiation (e.g., fuel depletion). The physical and chemical changes in fuel material during depletion and its impact on the cladding is a fuel performance problem.

Decades of code development have yielded the methods and procedures currently deployed for operating reactors that predict conditions during steady-state and transient scenarios (Duderstadt and Hamilton, 1976; Smith, 1980). Many of these methods leverage (1) the simplified pin- or plate-type fuel geometries of most operating reactors (Table 1) to use one-dimensional (1D) or two-dimensional (2D) models, (2) leverage axial coolant channel uniformity for thermal hydraulic models, and (3) adopt simplified methods such as point kinetics for dynamic modeling. In some cases, tools are more safety specific—as when applying uncertainty factors in calculating the margin to fuel failure—than predictive. The simplicity of these tools is useful for adhering to the software quality assurance rigor required for nuclear safety basis calculations.

The geometric complexity and design flexibility proffered by additive manufacturing are not amenable to the modeling and simulation used for more traditional reactor methods and tools. Predictive simulation is critical in leveraging geometric complexity and heterogeneity to improve performance over designs constrained by conventional processes. Ongoing advancements in nuclear modeling and simulation have already provided for consistent incremental changes in light-water reactor fuel assembly geometries to improve fuel cycle economy and reduce fuel failures. These improvements include more complex gadolinia rod loading patterns (Rearden and Jessee, 2016), axial fuel heterogeneity (Franceschini et al., 2015), and more complex water box geometries (Gustafsson et al., 2013). One example of these advanced methods is the main product of the Consortium for Advanced Simulation of LWRs (CASL), which targeted enhanced operational performance, efficiency, and safety of LWRs (CASL, 2019). This product uses a 2D/1D method with the assumption that the majority of the assembly heterogeneities are in the radial dimension, and axial heterogeneities may be captured using a simpler 1D solution (Kochunas et al., 2017).

The most high-fidelity methods for core design include high-fidelity Monte Carlo transport and computational fluid dynamics (CFD). These methods are most relevant for modeling the geometric complexities of additively manufactured components and generating best-estimate results for nuclear design activities (Fig. 5). While seen as intractable for core design applications due to computational expense, these methods have recently been applied in operating reactors (Betzler et al., 2017). Providing validation data for CFD simulations is necessary to verify the method for the application, and additive manufacturing serves well in rapidly generating components for testing. For thermomechanical analysis, a host of finite-element–based tools is available. For nuclear fuel applications, the MOOSE-based BISON tool developed by the DOE-NE Nuclear Energy Advanced Modeling and Simulation (NEAMS, 2019; Williamson et al., 2012) and maintained by Idaho National Laboratory, uses generalized equations and methods that are suitable for additively manufactured geometries.

Table 1 Power densities, fuel geometries, and active core height for selected reactor designs.

Fuel type	Typical core power density (kW/L-core)	Active core height (m)	Fuel geometry type
<i>Commercial reactor fuels</i>			
PWR	100	3.66	pin
BWR	50	3.05–3.66	pin
AGR (Nonboel, 1996)	3	8.30	pin
<i>Research reactor fuels</i>			
MTR (Miller and Sindelar, 1995)	varies	0.61	plate
TRIGA (Cammi et al., 2016)	varies	0.36	pin
VVR (Pond et al., 1998)	varies	0.60	plate
IRT (Hanan et al., 2006)	varies	0.60	plate
<i>High-performance research reactor fuels</i>			
ATR (Stanley and Marshall, 2008)	1000	1.18	plate
MITR (Massachusetts Institute of Technology, 2020)	70	0.57	plate
HFIR (Adamson and Knight, 1968)	1700	0.51	plate
NBSR (Diamond et al., 2015)	40	0.56	plate
MURR (University of Missouri, 2020)	300	0.61	plate

The fuel cross section area coincides with the color areas. Credit: Brian Ade and Danny Schappel. Ade BJ, Schappel DP, Betzler BR, Helmreich G (2020b) Particle packing characteristics in dense TRISO/SiC fuel elements and the impact on neutronics and thermomechanics. *Transactions of the American Nuclear Society* 123.

Optimization approaches that efficiently leverage these predictive high-fidelity simulations are critical in fully realizing the benefits that additive manufacturing technologies offer for a given application. Commercial optimization tools exist, with successful applications in optimization for fluidic or mechanical part performance (See et al., 2020). Application to the coupled nature of nuclear reactor multiphysics is more complex, requiring effective communication across several simulation tools. Some successes using emulators in place of high-fidelity physics to rapidly evaluate thousands of potential designs have been achieved (Hiscox et al., 2020; Sobes et al., 2019, 2020). However, more generic topology optimization for nuclear reactor core design applications is an open design problem characteristic of the advanced reactor development industry, which works with fewer design constraints relative to incremental fuel assembly design.

Future roles

Defining the qualification and regulatory processes for additive manufacturing technologies provides for more widespread adoption in highly regulated environments like those for critical nuclear reactor and core components. Efforts to apply additive manufacturing in the defense, aerospace, and medical fields are addressing these same issues (Babu et al., 2018; Horst et al., 2019; Seifi et al., 2017). The earliest proponents of nuclear reactor additive manufacturing applications exercised this process with regulator involvement to address unknowns and reservations associated with these new manufacturing practices (Hull et al., 2019). Demonstration of consistent material performance over long-term irradiations is critical for economically viable core-adjacent components.

Future prospects for additive manufacturing applications in the nuclear industry have been recognized and addressed through many activities under the Transformational Challenge Reactor (Cetiner and Ramuhalli, 2019; Nelson, 2019; Tobin et al., 2018) program:

- Developing manufacturing surveillance processes to record data that may be used to help understand material properties, predict performance, and meet specifications
- Deploying additive manufacturing technologies to facilitate the rapid manufacturing of replacement parts
- Redesigning components with additive manufacturing to improve performance and/or reduce cost
- Deploying additive manufacturing technologies for rapid prototyping to shorten development times for new designs
- Reimagining nuclear core design through the agile design process with additive manufacturing to optimize nuclear performance
- Embedding sensors inside of components to provide additional data during operation to monitor component performance over the lifetime of a part
- Developing heterogeneous fuel monolithic structures to improve performance (e.g., fuel utilization)
- Developing advanced matrices for particle and dispersion fuels free from conventional processes to accurately control distributions, increase matrix quality and packing fractions, and reduce design uncertainties

The data-rich processes and advanced characterization available with modern technologies (Fig. 6) decrease the timeline to deliver on additive manufacturing applications and to realize their benefits. Applications will continually gravitate toward higher performing parts in more challenging physics environments, including critical fuel components. Continued development of new materials, additive manufacturing methods, and advanced computation will only increase the applicability of these technologies to nuclear reactors.

Credit: Andres Marquez Rossy, Terrani KA, Jolly BC, Trammell MP, Vasudevamurthy G, Schappel DP, Ade BJ, Helmreich GW, Wang H, Marquez Rossy A, Betzler BR, and Nelson AT (2021) Architecture and properties of TCR fuel form. *Journal of Nuclear Materials*. <https://doi.org/10.1016/j.jnucmat.2021.152781>.

Implementation under the Transformational Challenge Reactor program

The US DOE-NE Transformational Challenge Reactor (TCR) program is the best representation of the integration of these different elements to drive additive manufacturing applications in the nuclear industry (Oak Ridge National Laboratory, 2019). These elements include the development of manufacturing processes and approaches, the collection of advanced in situ manufacturing data, the implementation of an agile design process, the use of high fidelity modeling and simulation tools for optimization, and the exercising of the qualification and regulatory processes. This leverages advances in numerous scientific areas—including materials, manufacturing, sensors and control systems, data analytics, and high-fidelity modeling and simulation—to accelerate design, manufacturing, qualification, and deployment of advanced nuclear energy systems. A core component of the program is to design, build, and operate a small nuclear reactor to fully integrate and rapidly demonstrate these elements in 4 years.

Following assessment of additive manufacturing technologies (Nelson, 2019; Simpson et al., 2019) and their applicability to nuclear reactor engineering problems (Tobin et al., 2018), the TCR program implemented an agile design process (Betzler et al., 2020b) to design and downselect a reactor design in less than 12 months of effort (Betzler et al., 2020a,e). The following maturation of the design with iteratively manufactured prototypes provided the as-built information necessary to further mature the design (Ade et al., 2020a,b). Advanced in situ characterization during prototype manufacturing provides the data necessary to support qualification activities (Scime et al., 2020). Design information provided to irradiation efforts ensure that design conditions are bounded in burnup and temperature (Coq et al., 2020; Kile et al., 2020; Vasudevamurthy et al., 2020).

Many of these design elements are effectively integrated in the agile design process. Under this process, data and constraints from manufacturing processes (e.g., minimum thicknesses, actual material densities, moderator impurities and stoichiometry) are incorporated immediately into the design activities to determine their impacts and sensitivities in relation to reactor performance. Collocation of key staff members at the Oak Ridge National Laboratory Manufacturing Demonstration Facility (ORNL, 2020) allows for consistent communication between materials, manufacturing, nuclear, thermofluidic, and thermomechanical experts and analysts. This collocation ensures direct access to additively manufactured prototypes and test components, as well as the experts operating the machines and performing characterization on manufactured parts.

Initial preconceptual design activities started with two simple guidelines: (1) to design, build, and operate an advanced nuclear reactor within several years, and (2) to leverage the fundamental characteristics of additive manufacturing to accelerate this process. Instead of establishing a preferred reactor technology early in the design process, technologies were assessed based on these guidelines, and technical decisions made heavily emphasized viability and simplicity in design. Processes and materials for powder bed fusion, laser-directed energy deposition, and binder jetting were assessed to determine their feasibility for nuclear applications (Simpson et al., 2019).

Drawings of the earliest preconceptual designs of the TCR core were sent to additive machines and were printed using candidate materials such as steel, SiC, and Inconel. The printed parts included the initial monolithic core structures, different types of stackable fuel elements, fuel element retention structures, and insulated-moderator core concepts (Betzler et al., 2020c). Design sprints focused on determining the feasibility of specific design features and testing additively manufactured materials (Field et al., 2019; Schappel and Terrani, 2019). Feedback from monitoring and characterization were implemented into physics models to determine sensitivities to tolerances and more detailed impacts from material distributions (Ade et al., 2020a,b).

Candidate designs were quickly developed and continually refined as requirements, constraints, and available technologies continued to evolve (Fig. 7). This includes key design decisions, including moving on from the earliest unmoderated preconceptual designs due to fuel constraints (Ade et al., 2020c; Betzler et al., 2020d), selecting a yttrium hydride moderator (Bergeron et al., 2020; Hu et al., 2020) and a TRISO in SiC fuel form (Terrani et al., 2020a,b; Trammell et al., 2019) as manufacturing and characterization

Fig. 7 Transformational Challenge Reactor fuel assemblies incorporating binder jetted silicon carbide fuel elements and powder bed fusion metallic components. Betzler BR, Ade BJ, Wysocki AJ, Chesser PC, Terrani KA (2020b) Transformational challenge reactor agile design enabled by additive manufacturing. *Transactions of the American Nuclear Society* 123.

rapidly progressed during the design process (Byun et al., 2020a,b), and selecting steel encapsulation for the yttrium hydride moderator to fit with the demonstration timeline. Flexibility and responsiveness of the TCR program design thrust was critical in accommodating these changing requirements and taking on these new technologies to advance this design in less than 12 months (Betzler et al., 2020a). This has produced a viable, simple design that incorporates novel fuel and moderator forms (Table 2) with embedded sensors (Petrie et al., 2019).

Constraints and working prototypes have been immediately shared with TCR program technical and programmatic leadership to help make technical design decisions. This close collaboration and tight feedback loop ensures that the developed design meets high-level requirements while also ensuring that the requirements are consistent with project scope, schedule, and other programmatic constraints, such as realistic availability of the type and quantity of fissile material. In addition, interested parties such as the regulator are kept apprised of new design developments. In the manufacturing area, representatives from potential future regulators are collocated to learn and about additive manufacturing processes and the advanced capabilities in characterization and monitoring.

High-fidelity Monte Carlo-based reactor physics, CFD, and finite element thermomechanical simulations are used in design efforts for optimizing core and fuel element geometries (Popov et al., 2020; Schappel and Terrani, 2019; Weinmeister et al., 2020). Safety analyses are performed with more traditional tools to determine conditions during postulated accidents and sensitivities to design parameters (Betzler et al., 2020e; Wysocki et al., 2020). The fidelity of these simulations has been iteratively refined

Table 2 General Transformational Challenge Reactor conceptual design characteristics.

Attribute	Value
Total power	3 MWt
Inlet coolant temperature	300 °C
Outlet coolant temperature	500 °C
Fuel	UN TRISO
Fuel enrichment	19.75%
Fuel element type	TRISO in SiC
Moderator	Yttrium hydride
Moderator encapsulation	Type 316L stainless steel
Coolant flow direction	Downward
Coolant type	Helium
Coolant pressure	5 MPa
Pressure vessel	Type 304H stainless steel
Control	External segmented shroud
Shutdown	Central rod

through the design process as more as-built information and tolerances have been fed back into the design. This iterative refinement provides the flexibility in the design process to continue to respond to feedback and changing design requirements. Observations from applications of artificial intelligence for more generic nuclear core optimization are incorporated into the design elements as they become available (Hiscox et al., 2020; Popov et al., 2020).

Conclusion

Continued development of additive manufacturing technologies will only widen their applicability in the nuclear reactor industry. Critical additively manufactured components are being deployed in many highly regulated industries, and core components are in use at operating reactors. Additively manufactured components are currently under irradiation in several reactors.

Despite these varied research and development activities, there are some inherent limitations of these technologies. A value proposition for the application of additive manufacturing does not exist for all reactor components. For example, additively manufacturing a long, thin fuel cladding tube is likely neither economically feasible nor possible. Specific technologies quickly become outdated due to the rapid progress made in additive manufacturing methods and technologies. In addition, these applications mainly address in-core reactor components which often do not represent a large cost relative to the entire reactor itself. For these reasons, applications of additive manufacturing in construction (Paolini et al., 2019) may provide the greatest economic impact for large reactors that require high quality construction processes.

Introduction

Many countries agreed to reduce their green-house gas (GHG) emissions to limit the global average temperature rise to less than 2 °C compared to pre-industrial levels under the Paris Agreement ([United Nations, 2015](#)). This would require major efforts to decarbonize the entire energy sector, given that the energy demand will continuously increase. International Atomic Energy Agency ([2019a](#)) estimates that the growth in electricity demand will outpace the estimated growth in total energy demand, which would imply major transformation of the electricity sector to carbon-free generating sources. The average GHG emissions from electricity production in OECD countries would require reduction from current level of 430 gCO₂ per kWh to 50 gCO₂ per kWh.

Technology improvements in wind turbine and solar photo voltaic (PV) have reduced their investment costs to the point that they are nearly competitive with natural gas generation, while the cost of building nuclear plants, one of the main low carbon alternatives, has remained high ([Massachusetts Institute of Technology \(MIT\), 2019](#)). With the falling costs and various policy incentives, wind and solar (so called “renewable”) technologies have dominated investment in the power sector globally in recent years. The incentives for the renewables ranged from tax incentives and renewable portfolio requirements as in the United States, to feed-in tariffs or zero emission credits ([MIT, 2019](#)). The main limitation on the renewable sources is the challenge of matching their daily and seasonal variable pattern of supply with the demand, as such these sources are also called as variable renewable energy (VRE) sources. The increasing use of intermittent renewables creates grid management challenges requiring the power system to be more flexible. Flexible operations in current nuclear plants lead to lower capacity factors and affect the economics adversely. Hence, it would not be in a utility’s interest—be it in a regulated or deregulated electricity market—to currently invest in a new nuclear reactor if it expects that it will be operating at relatively low capacity factor in order to meet flexibility needs of the power systems. The challenges of integration of advanced nuclear reactors with VRE sources, flexibility requirements and economic considerations for building new nuclear reactors are discussed in this article. This article also explores opportunities for deployment of advanced reactors through innovative approaches and policies that would be conducive to nuclear deployment.

Current challenges

The advent of abundant wind and solar energy sources is one of the main factors driving the transformation in the power systems. This transformation is compounded by the deployment of decentralized energy resources, including rooftop solar and smart loads such as electric vehicles and smart appliances ([International Energy Agency \(IEA\), 2018](#)). These changes are influencing the way the power systems are planned and operated.

Over the past two decades, nations introduced climate change policies to pursue lower GHG emissions, which included the adoption of variable renewables ([Nuclear Energy Agency \(NEA\), 2019](#)), incentivized in part by subsidies. Some countries, for example, Canada, France, Germany, United Kingdom and the United States, experienced an increasing share of renewable sources for electrical power generation as part of their climate change policies, as shown in [Fig. 1](#) based on data from [US Energy Information Administration \(2019\)](#).

Over the same timeframe of the last two decades, the share of nuclear power generation declined in Germany and South Korea, while Canada, France, the United Kingdom and the United States experienced relatively stable shares of nuclear power generation as shown in [Fig. 2](#), based on data from the [US Energy Information Administration \(2019\)](#).

The increasing share of renewable sources of electrical power generation has led to surplus baseload electricity generation, which has resulted in baseload sources operating at a lower capacity. In France, the nuclear reactors fleet of the Électricité de France (EDF) fleet provides more than 70% of the total electricity supply of France. Therefore, the entire French nuclear fleet operates flexibly to some extent, with all reactors participating in frequency services (up to $\pm 5\%$ of the rated power), and two-thirds of the plants used for load-following (with 5% per minute power ramp rates). The combination of load-following capabilities with the size of the nuclear fleet allows EDF to achieve significant shifting of the nuclear load that can reach more than 12 GWe of nuclear capacity over a few hours (i.e., 20% of French installed nuclear capacity).

Fig. 1 Increasing share of non-hydro renewables in electricity supply.

Fig. 2 Share of nuclear power in electricity supply.

In Germany, the renewable sources generate about 30% of the total electricity. Large variations in VRE generation requires nuclear plants to have enhanced load-following capabilities, which adversely affects the economics of nuclear power generation. The load-following capabilities were built-in at the construction of the German nuclear fleet but have only started to be used in response to renewables intermittency.

While the nuclear plants in France and Germany have been operating in flexible mode, not all currently operating nuclear plants can provide flexibility services required to accommodate high shares of VRE sources on the grid. Operational flexibility of nuclear plants not only depends on the original design considerations but also is dependent on the regulatory restrictions and electricity market structure aspects of generating power. Flexible operation of nuclear power plants, resulting from priority dispatch of renewable electricity result in reduction in capacity factors and thus affects the nuclear plant economics adversely.

In some instances, surplus generation from renewable resources has led to negative prices, where the nuclear plants had to pay to dispatch the power on the grid to keep the plants running.

Nuclear power plants are capital intensive and have lower fuel costs compared to fossil fuelled- plants and thus are more economical when operated at full power output rather than at modulated output. Reduced load factors due to flexible operation increases the average electricity production cost.

Integration of the renewable sources with baseload generators such as nuclear power plants makes the grid management more challenging. Forecasting errors in variable renewable output also requires carrying on a higher amount of spinning reserves in the system. Provision of physical inertia in a system with a high share of intermittent VRE sources is a topic of emerging research since the inertia is implicitly provided by the dispatchable plants and not by VRE sources. Hybrid nuclear-renewable energy systems,

large-scale energy storage and possibilities of using thermal energy as a coproduct from the advanced Gen IV reactors would mitigate the challenges discussed in the previous paragraphs and make the new nuclear reactors viable as a climate change solution.

Economic considerations for new nuclear

Levelized cost of electricity (LCOE) is often used to compare the cost of electricity generation from various sources and it is based on the plant-level costs (Rothwell, 2021). However, the cost of electricity provision to the consumer and to the broader society also includes the electricity system costs of transmission and distribution and maintaining grid reliability, as well as the cost of impacts on air pollution and climate change. Thus, the full cost of electricity provision includes three categories: plant-level costs, grid-level system costs and the external social and environmental costs. The NEA report (2018) concluded that the grid-level system costs associated with VRE generation are large and increase over-proportionally with the penetration level of renewables. In comparison, system costs of dispatchable technologies, such as nuclear, are at least one order of magnitude lower. However, the share of VRE in electricity generation has continued to grow globally. It must be noted that the plant-level costs for VRE tend to be lower because of the tax credits and these low costs are often passed on to the consumers; however, the consumer ultimately bears the cost in terms of higher deficits and higher taxes to compensate for the tax credits for renewables (MIT, 2019).

Integration of VRE sources into the existing grids with dispatchable electricity generating sources has been widely studied. MIT report (2019) compared the possible scenarios under the US electricity-sector policy to reduce CO₂ emissions by 90% in 2050 compared to 2005 level. The MIT study concluded that the additional system costs of wind and solar are minimal until they reach about 40% of power supply, but after that level these extra costs rise, making room for other power technologies such as nuclear, which can significantly reduce the carbon price needed to achieve deep decarbonization of the electricity-sector in the United States. In the absence of low-carbon, low-cost advanced nuclear alternative, it will require substantial carbon price to achieve the emissions target because the intermittency of renewables will require a combination of redundant renewable capacity with significant curtailments, energy storage and flexible gas capacity. However, the availability of advanced nuclear reduces the needed carbon price in the power sector from near \$120 per ton (2006 \$) of CO₂ without nuclear option to under \$40 per ton (2006\$) of CO₂ to achieve 90% emission reduction by 2050. Another NEA study (2019) also assessed the costs of alternative low-carbon electricity systems capable of achieving strict carbon emission reductions to 50 gCO₂ per kWh with different shares of renewable and nuclear resources. The NEA study shows that the system costs of electricity provision increases with increasing share of VRE in the electricity mix. Since the load factor of VRE is significantly lower than the conventional thermal (nuclear and fossil) power plants, a significantly higher total generation capacity is required to produce the same amount of electricity. The NEA study also found a striking effect of the deployment of low marginal cost VRE sources on the electricity market with increase in the volatility of the electricity prices. The number of hours with zero electricity prices increase with increasing penetration of VRE, starting with 60 hours per year of zero price at 30% VRE penetration increasing to 3750 hours per year of zero price at 75% VRE penetration. Yet another market effect of increase in the share of VRE is the decrease in the average price of electricity generated by the VRE, because all wind and PV solar generation will be concentrated in limited number of hours, producing disproportionately more electricity.

Electrical Power Research Institute (EPRI) analyzed (EPRI, 2018) the economic drivers and barriers for the advanced nuclear reactors in the future energy markets in the United States. The analysis found that the deployment of the new advanced reactors in the United States would require lower cost technology options and favorable policy environment (for example, carbon pricing), supplemental revenue streams (such as process heat sales), or a combination of these factors. EPRI analysis considered various scenarios around a range of advanced reactor capital costs, natural gas prices, environmental policy (carbon pricing) and additional non-electricity revenues (process heat). Capital costs ranged from \$2000 per kW to \$5000 per kW, although the high value is still considered lower than the cost of new light water reactors. The scenarios favoring deployment of advanced nuclear reactors generally included lower capital costs, particularly in the absence of new environmental policies with low natural gas price environment in the United States. Strong environmental policy and additional non-electricity revenues could tolerate higher capital costs for nuclear.

Another recent MIT study (MIT, 2018) found that new nuclear plants are not a profitable investment in the United States and western Europe. The high cost of new nuclear plants is a significant constraint to the growth of nuclear power under the scenarios of “business-as-usual” and modest carbon emission constraints. The MIT report shows that the overnight capital cost (\$ per kW) for recent Generation III+ reactors in the United States and western Europe are 30–70% higher than the 2009 benchmark of \$5000 per kWh. World Nuclear Association (WNA) also reported similar significant overnight cost increases for the PWR and BWR type reactors in North America and western Europe compared to East Asia (WNA, 2017).

The MIT report (2018) also recommended Government funding programs around prototype testing and commercial deployment of advanced nuclear reactors. The MIT report also analyzed attributes for successful nuclear build projects and cost drivers for those projects. The report recommends focusing on proven project and construction management practices to increase the probability of success in the execution and delivery of new nuclear plants. It further notes that the advanced reactors are expected to utilize compact and simpler designs to reduce cost and capture new markets such as process heat.

Generation IV International Forum (GIF) issued comprehensive cost estimation guidelines (GIF, 2007) for nuclear reactors. Advanced nuclear reactors represent dramatic evolution from the conventional reactors and there is a great uncertainty in the cost estimates in the absence of any commercial projects. Energy Options Network (EON) used the cost estimation framework of the GIF and worked with the leading advanced reactors companies to obtain reliable, standardized cost projections of their Nth-Of-A-Kind (NOAK) plants (EON, 2017). The reactor types being developed by the advanced reactors companies included

the reactor types being developed under the GIF collaborations. The average total capital cost in 2016 dollars for the advanced nuclear reactors was estimated to be \$3782 per kW installed capacity compared to the benchmark PWR cost of \$6755 with uncertainties ranging from $\pm 10\%$ to $\pm 50\%$. It should be noted that the benchmark PWR is NOAK type, while the new PWRs built as units 3 and 4 at Vogtle in the United States are considered as First-Of-A-Kind (FOAK) and could have significantly greater costs. While acknowledging the uncertainties in the cost, the report highlights the strategies being pursued by the advanced reactors companies to reduce the capital cost including:

- simpler and standardized plant designs
- factory fabrication
- lower materials requirements
- modularization
- reduced scope for engineering, procurement and construction
- shorter construction time
- higher power density
- higher efficiency.

The EON study found the average LCOE for advanced reactors to be US\$60 per MWh compared to the benchmark PWR LCOE of \$97 per MWh.

Although there is no specific definition of NOAK plant, it is supposed to reflect improvements and cost decline with each doubling of experience until the capital cost reaches an asymptotic value for the plants supplied by the same vendors and contractors. According to GIF cost estimation guidelines (GIF, 2007), the NOAK costs are achieved for the next plant after 8 gigawatts (GWe) of capacity have been constructed of a nuclear energy system. While 8 GWe criteria could have been based on the historical trend for conventional reactors, the learning factors could be different for the advanced reactors which could use factory-fabrication and modularization techniques. Learning factor represents capital cost decline with each doubling of experience in construction of nuclear plants and is related to the capital cost by the following equation.

$$C_N = C_1 \left(Lf^{\frac{\ln(N)}{\ln(2)}} \right)$$

where, C_N = capital cost of Nth plant, C_1 = capital cost of FOAK plant, Lf = learning factor.

Fig. 3 shows the evolution of capital cost of nuclear plants with learning factors of 0.95 and 0.975 representing cost declines of 5% and 2.5%, respectively, for each doubling of the experience.

Energy Technologies Institute (ETI) analyzed the cost drivers for the nuclear plants to better understand the schedule delays and cost increases for recent new projects in North America and Europe in contrast to those built elsewhere in the world (ETI, 2018). Reducing the capital cost requires reducing the project risks by increasing certainties in project schedule and budget. ETI report makes several recommendations to reduce the capital costs, including completion of the design prior to starting the construction. The ETI report also identified the potential step-reduction in the cost of advanced reactor technologies and small modular reactors (SMR), some of which are like those listed above.

In summary, a major consideration for the successful deployment of advanced reactors would be to reduce the capital costs which consists of two main components.

- *Capital (overnight) cost*: which can be potentially reduced through modularization, factory fabrication, design simplification and improved project management. Overnight capital cost includes all costs incurred before the plant is ready to start earning

Fig. 3 Cost evolution of nuclear plants with learning factors.

revenue, except the time-value cost of the capital (interest during the construction). It can be considered as the cost incurred if the plant was constructed overnight without accrual of interest.

- *Cost of capital*: which requires favorable policies to finance nuclear projects to reduce the interest during the construction, as discussed later in this paper.

Flexibility requirements for new nuclear

Utility expectations

Electricity demand on a power system varies with time and the changes could occur on a short duration (seconds to minutes) or long duration (daily, weekly, seasonal). These demand changes are caused by the demand variation with time (day versus night, working day versus weekend), and weather conditions (summer versus winter). Typically, power system or grid operators manage the electrical supply to the consumers by forecasting the demand. They then schedule ramp rates needed to match the forecasted demand. Finally, they provide regulation service to correct discrepancies between scheduled and actual load, and load and generation, while maintaining frequency and voltage on the grid.

In addition to the demand variation, increasing integration of VRE sources also add challenges of supply variation which must be managed by the system operator. For the systems that allow priority dispatch for the VRE sources; the other dispatchable generating stations (nuclear, fossil, etc.) are required to have enhanced ramping and load following capabilities.

The Clean Energy Ministerial (CEM), a multinational initiative with current membership of 26 nations, launched the advanced power plant flexibility campaign in 2017 to commit the governments to make the power generation more flexible to allow integration of VRE sources into the power systems. As part of this campaign IEA published a report (IEA, 2018) that highlights the role of power plants in system flexibility and policies required to advance power system flexibility. Although not specific to the nuclear plants, the IEA study looked at the limitations of the current generation nuclear plant and options to enhance the flexibility but did not consider the advanced reactor concepts that are under development. Recently, the CEM also launched flexible nuclear campaign in 2019 with the objective of modeling revenue opportunities for flexible nuclear plants in various parts of the world to inform the government stakeholders as well as the designers of Gen IV reactors.

The utilities in Europe and the United States issued requirements for the advanced light water reactors (Gen III+) (EPRI, 2014) that demand the new nuclear plants to be capable of providing flexibility to the system. These utility requirements are mainly focused on operational flexibility of the nuclear plants. A typical expectation of daily power variation of new nuclear plant is depicted in Fig. 4.

The advanced Gen IV reactors are significantly different compared to Gen III/III+ reactors and use different fuels and different coolants and operate at higher temperatures: making it suitable for applications beyond electricity production. Therefore, to evaluate the flexibility of Gen IV type reactors, EPRI proposed expanded flexibility criteria (EPRI, 2017). EPRI's expanded flexibility criteria consists of a set of three sub-criteria, each having specific attributes as follows:

- operational flexibility
- deployment flexibility
- product flexibility.

The above criteria of flexibility are discussed in further details below.

Fig. 4 Typical daily power variation of a flexible nuclear power plant.

Operational flexibility

The operational flexibility is generally understood as the ability of the nuclear power plant to respond to the variability of demand from the grid while maintaining the power quality. In addition to maneuverability, EPRI (2018) proposed other attributes of flexibility for advanced reactors systems, listed below.

1. *Maneuverability*: the ability to meet the ramping requirements for the grid and providing frequency control.
2. *Compatibility with hybrid systems*: The ability is considered important particularly for integration with VRE sources through hybrid energy systems which may include energy storage and other energy applications.
3. *Diversified fuel use*: The ability to operate using different types of fuel.
4. *Island mode operation*: The ability of the advanced reactor system to operate in isolation from electricity distribution networks.

The ability of a light water reactor (LWR) to provide flexibility services depends on the fuel condition. Typically, the LWRs do not participate in ramping for a few days (depending on the reactor and fuel design) after refueling until the fuel is conditioned. Fuel rods are manufactured with a prescribed gap between the fuel pellet and the inside cladding wall. During the reactor operation, the gap may reduce and lead to pellet-cladding interaction (PCI) which could lead to cladding failure. Load following operation could change local power density and cause PCI. Fuel vendors generally provide guidance on restricting flexible operation early in the fuel cycle until the fuel is conditioned to avoid PCI induced cladding failure. The reactors also do not operate in flexible mode towards the end of the fuel cycle due to limited excess reactivity to overcome xenon poisoning. Advanced fast reactors will not have xenon limitations experienced by the LWRs. In the case of gas-cooled reactors, the thermal fluctuations are avoided by controlling the coolant flow with the required power fluctuations, thus preventing ageing of components due to thermomechanical stresses. Advanced reactors are also flexible in terms of fuel; for example, the liquid fuels for molten salt reactors provide inherent fuel flexibility.

Deployment flexibility

The deployment flexibility is the ability of an advanced nuclear reactor to be licensed, financed, sited, and built under a range of external conditions. EPRI (2016) describes three attributes of deployment flexibility.

- *Scalability*: The scalability is the ability of an advanced reactor system to be sized to match energy demand, and to meet other local and regional requirements or to have the ability to be resized to increase energy output to meet changes to accommodate any growth in demand.
- *Siting*: Siting flexibility is described as the compatibility of an advanced reactor system with a variety of host locations, environments and conditions.
- *Constructability*: Constructability is described as the relative ease of building an advanced reactor system on schedule and within budget.

Product flexibility

Product flexibility refers to ability of the advanced reactor systems to be used for multiple missions. Most of the current nuclear plants produce electricity, although over 70 reactors world-wide have been used in cogeneration mode for various applications including district heating, providing industrial steam and for water desalination. Cogeneration is the term used for simultaneous production of electricity and thermal energy. In the case of nuclear power plants, the thermal energy use to date accounts for a small fraction (<1%) of the cumulative output of the nuclear power plants. Nonetheless, the individual thermal energy applications varied from 5 to 240 MWth.

Type of potential applications of nuclear thermal energy depend on the outlet temperature of the nuclear reactor. Past and current experience with nuclear cogeneration relates to lower-temperature applications such as district heating, sea-water desalination and process steam for industrial applications. The higher temperature advanced reactors would enable many more industrial applications including hydrogen production and petroleum refineries. Fig. 5 shows the advanced reactor temperatures and potential industrial applications. Cogeneration opportunities for advanced reactor systems are discussed later in this article.

Innovative approaches

Hybrid energy system

Hybrid system concepts were proposed to integrate nuclear with VRE sources to improve both the reliability of power and economics of integrated system. A hybrid energy system may be broadly defined as a single facility or cooperatively controlled system that integrates two or more energy inputs and produces one or more products, with an energy commodity such as electricity or transportation fuel (Ruth et al., 2014). Hybrid energy systems, which have a common grid for both variable renewable and dispatchable sources with storage possibility, to generate both heat and electricity, have been proposed as a way to integrate renewables with nuclear reactors by seeking new outlets in order to compensate for lower load factors.

Fig. 5 Potential cogeneration applications of advanced reactors.

Fig. 6 Nuclear-renewable hybrid energy system.

Hybrid energy systems are comprised of multiple sub-systems, as depicted in Fig. 6, which may or may not be geographically colocated (Bragg-Sitton et al., 2016):

- nuclear heat generation source,
- a turbo-generator for conversion of thermal energy to electricity,
- at least one renewable energy source (VRE),
- an industrial process that utilizes heat and/or electricity from the energy sources to produce commercial-scale product, and
- energy storage (thermal and/or electrical).

Hybrid energy systems can be configured in various ways, for instance, as a tightly coupled system which acts as a single financial entity where nuclear generation and VRE sources and industrial production are controlled upstream of a single connection point to meet the flexible demand from the grid while operating the nuclear plant at capacity.

The key benefits of hybrid energy systems are:

- provide dispatchable, flexible, and carbon-free electricity generation

- provide synchronous electromechanical inertia to the grid (frequency control), and
- reduce carbon footprint of industrial production.

Although fully integrated hybrid systems have not yet been demonstrated, the component technologies are mature. There has been an increased interest in exploring the synergies of nuclear and renewable energy sources and hybrid systems are promising to provide the required flexibility for integration. The secondary output of the hybrid system, such as thermal energy for industrial use or hydrogen as a commodity, is highly dependent on the location. Several national approaches for nuclear-renewable hybrid energy systems were discussed in a technical meeting organized by IAEA (2019b). The viability of a hybrid system will depend on the geographical location and the business model.

Cogeneration

Use of nuclear thermal energy for non-electricity applications have been widely studied and published (IAEA, 2009, 2012, 2017a,b) with main motivation to reduce GHG emissions. More recently, nuclear cogeneration is also being considered for integration of nuclear plants with VRE sources on the grid for improving economics of nuclear operations.

As shown earlier, in Fig. 5, type of potential applications depends on the temperature of the thermal energy delivered by the nuclear reactor.

Low-temperature non-electric applications

Low-temperature non-electric applications are typically those requiring thermal energy at less than 300 °C, which can be supplied by most of the existing reactors and Gen III+ reactors.

Desalination

Sea-water desalination capacity around the world is increasing rapidly to meet the increasing demand of fresh water in both developed and developing countries. Most of the desalination plants depend on fossil fuel and thus are subject to fuel price fluctuations and supply reliability, which could undermine its economic viability. Nuclear desalination has been demonstrated, can be economically competitive and meet the product water quality through a meticulously designed coupling system between a nuclear reactor and a desalination plant. Although the current generation reactors can meet the energy demand and temperature requirements for all sea-water desalination technologies, some of the advanced reactors are also being proposed for this service.

In Aktau, Kazakhstan, 10 units of multi-effect distillation (MED) plants were coupled to a 1000 MWth sodium cooled, fast breeder reactor (BN-350) (IAEA, 2017b). It produced 14,500 m³ per day of very high-quality water for industrial and potable needs and ran for 26 years before shutting down in 1999. Sodium-cooled fast reactors are also being developed as Gen IV advanced reactors.

District heating

District heating systems exist in many countries in Europe and in North America that have harsh winters. Many of these systems are fossil-fuelled. There has also been a gradual shift to decentralized heating for individual houses or buildings because of low natural gas prices. District heating systems are usually based on either hot water or low-pressure steam and range in size from 600–1200 MWth for large cities down to 10–50 MWth for smaller communities. With increasing environmental concerns over the use of fossil fuels, the alternate district heating is being considered. Total heat demand for district heating is significant and could require hundreds of nuclear reactors (IAEA, 2017b).

As of 1998, 46 commercial nuclear plants in 12 countries were being used or have been used for heating purposes with a heat output between 5 and 240 MW, demonstrating a safe and reliable operation (IAEA, 2017b). One example of pressurized water reactor which is run in a cogeneration mode for district heating is Beznau nuclear plant in Switzerland. Beznau plant began to supply nuclear district heating in early 1980s and continues to do so today, serving a population of nearly 20,000. The peak district heat load is about 80 MWth. Experience in Switzerland shows that nuclear-based district heating is economical, safe, reliable and can be acceptable to public.

Other low-temperature applications

Unlike desalination and district heating, there has been limited use of nuclear heat for industrial applications. The largest such application was the use of medium pressure steam from the Bruce nuclear power plant for heavy water production in Canada (IAEA, 2017b). Bruce-A nuclear plants had the largest bulk steam system ever built, with a capacity of 5350 MWth and supplied ~750 MWth for heavy water production, 15 MWth for on-site building heating and about 72 MWth to an industrial park with food processing, ethanol and plastic film manufacturing plants. The heavy water production plants were located near the nuclear power plant and were licensed by the Canadian regulator and operated from 1973 until 1997. In Switzerland, Gosgen nuclear plant supplies about 45 MWth thermal energy to a cardboard factory and a paper mill, using medium pressure steam (1.2–1.5 MPa).

Advanced Gen IV reactors that are under development present additional opportunities for industrial applications because of higher outlet temperatures compared to the existing reactors. A comprehensive study of European industrial heat market (Bredimas, 2004) focused on application of high temperature reactors for industrial cogeneration, identified significant low-temperature thermal energy demand that can be provided by either Gen III+ or other types advanced Gen IV reactors.

High-temperature non-electric applications

High-temperature non-electric applications require thermal energy supply at temperatures above 300 °C and therefore are non-existent due to the limitation on reactor outlet temperature of existing reactors. Ongoing development of advanced reactors with significantly higher temperatures has created possibilities of using nuclear heat for additional industrial applications.

Hydrogen production

Hydrogen has long been considered as an energy carrier but has not made much impact in the total world energy supply because of the practical difficulties of introducing hydrogen in the energy system. To be used as energy carrier, hydrogen must be produced using a primary, low-carbon source of energy and the energy efficiency of the production process must be such that hydrogen can be economically deployed as an energy carrier. Over 90% of the hydrogen currently produced is from fossil raw materials such as natural gas, using fossil fuel as source of energy; and is primarily used in chemical production plants. Only a small fraction of hydrogen is currently used in the energy sector, mainly in fuel cells for electricity production or in vehicles.

High-temperature water-splitting processes for hydrogen production are being developed alongside the development of high-temperature reactors. GIF has a special project for development of high-temperature hydrogen production processes as part the development of the Very High Temperature Reactors (VHTR) (GIF, 2002). The high-temperature processes include thermochemical cycles (such as sulfur-iodine and copper-chlorine) and high-temperature water electrolysis (HTSE) (IAEA, 2009).

Japan Atomic Energy Agency (IAEA) has operated a 30 MWth, helium-cooled high temperature test reactor (HTTR) and has also developed sulfur-iodine thermochemical process for hydrogen production (Yan et al., 2018). One of the main uses of hydrogen in Korea is envisaged to be for steel making using direct reduction of iron ore. At USDOE's Idaho National Laboratory, a high-temperature steam electrolysis (HTSE) process is being developed for hydrogen production using high-temperature reactor (O'Brien et al., 2010). Much research has also been done in exploring large scale hydrogen storage in salt caverns.

Ability of converting hydrogen back to electricity using fuel cells offers additional flexibility for nuclear plant operation as the hydrogen can be used both as energy storage as well saleable product.

Other high-temperature applications

High-temperature cogeneration opportunities for high-temperature reactors were investigated as part of the European Union-supported EUROPAIRS project (Bredimas, 2004; Futterer et al., 2014). The EUROPAIRS study found that almost one third of the European industrial heat market is "externalized" in the form of cogeneration, limited to 550 °C, particularly in the chemical, plastic, pulp and paper industries. This market can be captured by a "plug-in" high-temperature reactor, replacing the existing fossil-fuelled operations. The study also found a significant potential "pre-heating" market potential of nuclear energy for high-temperature industrial applications such as, iron and steel, glass and cement manufacturing. The EUROPAIRS study also looked at "Polygeneration" sub-market involving production of base raw materials such as industrial gases (hydrogen, nitrogen, oxygen) in addition to cogeneration of heat and power. Polygeneration could provide additional flexibility for nuclear power plant and improve its economics particularly for integration with VRE sources, while easing the siting restrictions for the plant. Various studies of potential cogeneration of high-temperature reactors for petrochemical and steel sectors are also summarized in an IAEA report (IAEA, 2012).

Although various cogeneration possibilities for high-temperature reactors have been studied; the challenges of economic competitiveness, licensing aspects of colocation and coupling of nuclear plant to a production plant and public acceptance have not been explored in detail.

Energy storage

Energy storage systems have been used over the past several decades and have helped the reliability and flexibility of the power systems. Pumped-hydro energy storage has been widely deployed throughout the world and represents more than 99% of the worldwide bulk storage capacity (Luo et al., 2015). One of the main contributions of the bulk energy storage systems has been in meeting the peak load demand. During the peak periods, power supply from base-load generators must be complemented by more-flexible but less economic oil- or gas-fired generators. The bulk energy storage systems provide the utilities with a means of providing economical alternative to meet the peak load demand without additional GHG emissions. Pumped-hydro systems have also been used for frequency control purposes by providing a large amount of power when generated electricity is in short supply. Apart from the pumped-hydro systems, other types have also been successfully deployed, including the batteries, compressed-air system, flywheels, and thermal energy storage.

The increasing penetration of VRE sources have created emerging market needs for energy storage systems. Although pumped-hydro systems are matured, the potential for further deployment is restricted by the availability of suitable geographic locations. There have been advances in the alternate technologies for energy storage. As discussed in the previous section, technologies for GHG-free production of hydrogen using nuclear energy are under development and present yet another option for energy storage in conjunction with hydrogen fuel cells. Thermal energy storage is claimed to be significantly less expensive compared to the electrical energy storage. Thermal energy storage using steam accumulators and sensible heat storage using oil and molten salt have already been deployed and other options for large-scale sensible heat storage are being investigated (MIT, 2017).

The available energy storage technologies are shown in Fig. 7.

Fig. 7 Energy storage system technologies.

The energy systems described in [Fig. 7](#) span across a range of capacities and applications. Selection of energy storage for an application is based on the following considerations:

- power rating (MW) and power density (MW per m³)
- energy content (MWh)
- response time
- storage duration (minutes to days)
- energy loss (% per day)
- cycle efficiency (%)
- lifetime (years)
- maturity of technology
- energy cost (\$ per kWh) and capital cost (\$ per kW).

A comparison of various energy storage systems is presented in by [Luo et al. \(2015\)](#).

Large-scale energy storage would enable integration of advanced nuclear reactors with the VRE sources and would provide the required grid flexibility and reliability. Such energy storage systems would also enable deployment of hybrid energy systems discussed earlier. Thus, the innovative approaches discussed in this section, including hybrid energy systems, cogeneration applications using nuclear thermal energy and simultaneous development of large-scale energy storage would facilitate deployment of advanced reactor systems in the future energy markets.

Policies required for nuclear deployment

Various policies have been tried out and/or implemented in different jurisdictions to encourage GHG reduction ([Mendoza et al., 2018](#)). As discussed earlier in this article, some of the policies such as market liberalization and priority dispatch for renewables could adversely affect the economics of nuclear generation. However, some other policies may improve the economics of nuclear generation and could be conducive to future nuclear deployment. Policy issues to enable nuclear deployment include taxes and credits, electricity pricing, and financial arrangements.

Carbon taxes and zero emission credits

In response to the possibility of a premature closure of nuclear power plants some jurisdictions considered implementing zero emission credits which are like renewable energy credits ([Nuclear Energy Institute, 2018](#)). For example, New York, Illinois, Connecticut, New Jersey, Ohio, and Pennsylvania in the United States allow utilities with nuclear power plants to apply for such credits ([Tsai and Gülen, 2017](#)). The value of the zero emission credits varies among the jurisdictions. In the case of New York, the zero emission credits are first purchased by the load serving entity, and the cost of the credit is recovered from customer bills. Such programs have been challenged, and in some cases, the challenges have been dismissed, though there continues to be opposition to such programs.

A potential issue for nuclear is that zero emission credits are based on power generation each year. If the share of renewables increases, then the total value of the zero-emission credit from nuclear power generation may decline over time, especially in jurisdictions that provide priority for renewables. Another potential issue is that the timing of receiving the credit may not come quickly enough to offset the rising costs of generating power as the renewable share of electricity generation rises, which may require additional debt load if revenues are declining and there is insufficient working capital.

A carbon tax is a tax set by government in terms of dollars per ton of carbon dioxide (CO₂) emitted. The carbon tax is part of annual costs incurred by a utility. The introduction of a carbon tax would likely make nuclear more competitive (EPRI, 2018; NEA, 2011). Different carbon taxes may be adopted by different regions to enable nuclear power more competitive. Regional differences can reflect different manufacturing culture, environments for regulation and public acceptance of nuclear plants. Furthermore, break-even carbon tax will depend on the prices of fossil fuels in different regions of the world.

As discussed earlier, EPRI analysis (EPRI, 2018) of the economic drivers and barriers shows that strong environmental policy and carbon taxes would favor deployment of advanced reactors in the future energy markets in the United States.

Electricity pricing and market structure

Nuclear power plants struggle in the liberalized markets, firstly with competition from low-natural gas prices and secondly with the over-production from VRE sources which tend to drive down the market price. In order to offset the volatility of wholesale market prices and potential decline in prices, a fixed contract may be used when an electric utility with nuclear power generation must use load following mode. Guaranteed long term electricity contractual agreements, for example, strike price in the United Kingdom, and Power Purchase Agreement for Bruce Power in Canada (Barkatullah and Ahmad, 2017; Lucet, 2015) would ensure economic viability of nuclear and would spur further investment in new nuclear plants.

The appropriate wholesale electricity price should account for both the energy market and the capacity market to provide an incentive for utilities to meet the demand for energy and reserves. Liberalized markets consider energy-only electricity pricing. Under an energy-only pricing scheme, however, wholesale energy market pricing does not account for the value of reliability.

Financing of new nuclear

As discussed earlier, building a new nuclear plant is capital intensive project and to ensure successful deployment requires both reducing the overnight capital cost and the cost of the capital. Financing nuclear power project remains a challenge today. Raising capital for new nuclear plants will be more challenging in markets where nuclear is required to be integrated with renewable sources on the grid which may cause low capacity utilization of the plant.

Even though the government's financial role still dominates the deployment of new reactors, governments are looking for private sector participation. Private financing schemes used are corporate financing, investor financing, and vendor financing. Private sector financing has gained some momentum but is still constrained by the consequences of the 2017–18 global financial crisis, which limits financing, still seeks government support, and puts a risk premium on nuclear projects based on past performance (Barkatullah and Ahmad, 2017). Reducing project and liquidity risks are, therefore, important factors to consider for future research. New financing mechanisms will be vital for the deployment of future nuclear builds. In this regard, the regulated asset base (RAB) model has been proposed in the United Kingdom as an alternative to using a strike price and direct investment for financing a new nuclear reactor deployment (Helm, 2018). Strike price is the agreed price of electricity under a long-term Contract for Difference (CfD) between the nuclear plant owner and the electricity distributor, usually publicly owned. If the market price is lower than the agreed strike price, the government pays that difference to the plant owner and passes on the cost to the consumers. If the market price is above the strike price, generator pays the difference to the electricity consumers by reducing the tariffs. RAB models are used in the United Kingdom for funding monopoly infrastructures, where a regulator grants license to a company to charge a regulated price to the users of the infrastructure. RAB model has potential to reduce the cost of raising private finance for new nuclear projects, thereby reducing costs to the electricity consumers.

The Expert Finance Working Group (EFWG) set up by the UK's Department of Business, Energy and Industrial Strategy looked at what was needed to attract private financing to small modular reactor projects (EFWG, 2020). The EFWG recommends that the Government should help to de-risk (perceived and real risks) the small nuclear market in order to enable private sector to develop and finance projects. Reducing the risks of the projects and making the consequences of the risk manageable are fundamental to creating the best environment for the private sector to be able to invest in small nuclear.

Canadian Small Modular Reactor Roadmap, 2018 also recommended government funding to cost share with the industry in one or more SMR demonstration projects for advanced reactor designs. It also recommends that the government share risk with the private investors to incentivize the first commercial deployment in Canada.

Summary

Main challenges for deployment of advanced nuclear reactors in the future low-carbon energy market would be integration with the VRE sources and economic competitiveness. The developers of the advanced reactor systems are already exploring the means of reducing the investment cost through innovative fabrication and construction techniques. The Gen IV system developers are also taking into consideration the flexible operation requirement and associated thermal cycling and fatigue, reactivity control and fuel optimization at the design stage.

Various innovative approaches are also being explored to enable deployment of advanced reactors. Nuclear-renewable hybrid energy system concepts would provide successful integration of nuclear with renewables while ensuring economic viability of the project. The higher outlet temperatures of Gen IV reactors present opportunities for using thermal energy as an alternative

product to electricity to replace use of fossil fuels for process heat. Ongoing development of large-scale energy storage and technologies for producing hydrogen using nuclear energy would also enable Gen IV reactors to meet the flexible demand from the grid while operating the power generators to full capacity, thus, ensuring overall economically viable operation.

On the other hand, policy- and market-driven challenges could be more formidable compared to technical challenges of designing the reactors for flexible operation. Existing market designs do not always value reliability aspects of supply. Significant policy changes will be required to recognize and value reliability of nuclear generation as part of a resilient and reliable power grid. Favorable policies related to carbon taxes, electricity pricing and financing would ensure successful deployment of advanced nuclear reactors in the future energy market and would significantly help towards meeting the climate change goals.

Ehud Greenspan

University of California at Berkeley
gehud@nuc.berkeley.edu

Professor Greenspan (Ph.D., 1966, in Nuclear Science and Engineering from Cornell University, Ithaca, N.Y., USA) retired from the Department of Nuclear Engineering of the University of California at Berkeley (UCB) in 2014 but served as a Professor in the UCB Graduate School until 2019. He has nearly 60 years of nuclear energy related research experience starting in 1961 as an M.Sc. student at the Department of Nuclear Engineering of the Israel Institute of Technology. His research spans a wide range of nuclear engineering related disciplines including: theoretical and experimental reactor physics; computational methods development including development of new optimization methods for determining the minimum critical mass and for finding optimal design of radiation shields, fusion reactor blankets and medical installations; conception and analysis of advanced fusion fuel cycles and of fusion-fission hybrid reactors; as well as advanced fission reactors and nuclear fuel-cycle conception, design and analysis. The latter activity was the focus of his research during the last twenty-five years. The thrust of this

research is improving sustainability of nuclear energy along with improving economics, safety, and proliferation resistance. He has been the Principal Investigator on studies of dozens of advanced nuclear systems, including those corresponding to Generation-IV reactors and to Small Modular Reactors (SMRs). He was one of the early advocates of SMRs and led a multi-institutional international team that developed a preliminary conceptual design of the Encapsulated Nuclear Heat Source (ENHS)—an innovative nuclear battery-type SMR that is free of pumps, pipes and valves in the primary reactor system. The advanced reactor technologies addressed in his research include: heavy water reactors, pressurized and boiling water reactors, prismatic and pebble-bed liquid-salt cooled reactors, molten-salt reactors, sodium and lead-alloy cooled fast reactors, breed-and-burn reactors, heat-pipe reactors as well as fusion-fission hybrid reactors and accelerator driven nuclear reactors. His research is documented in over 400 refereed publications, over 200 non-refereed publications, 5 book chapters, and a number of patents.

Introduction

From the beginning of the Universe through to the present day, nuclear energy, nuclear reactions, and nuclear radiations have played major roles in the evolution and shaping of our universe and planet Earth. All the chemical elements we find on Earth were produced by nuclear processes in the Universe. Planet Earth is continuously exposed to nuclear radiation from primordial radioactive isotopes produced in cosmological processes that followed the Big Bang. A number of primordial radioactive isotopes are still among the Earth's constituents, including thorium ^{232}Th , the uranium isotopes ^{235}U and ^{238}U as well as potassium ^{40}K . The spontaneous radioactive decay of the nuclides of these isotopes releases nuclear energy that provides a major contribution to the heat balance of planet Earth. The internal heat source is responsible for keeping the outer core of the Earth in a molten magma state and played a major role in the geologic evolution of the Earth's continents and oceans. The primordial radiation and Earth's heat source may have also contributed to the creation as well as evolution of life on Earth. Since its birth, the Earth has been also constantly bombarded by galactic cosmic nuclear radiation, which primarily consists of protons (hydrogen nuclei) and alpha particles (helium nuclei). Hence, mankind as well as any organism on Earth, were and are being continuously exposed to background nuclear radiation throughout their evolution. The background radiation level as well as the radioactive heat source due to the decay of the primordial radioactive isotopes were significantly higher at the time of Earth formation and are slowly decreasing with time.

It is only within the last hundred and twenty years or so that mankind discovered the structure of the atom and its nucleus and learned how to harness the enormous energy potential contained within the nucleus as well as the different types of radiation nuclei and atoms can emit. Nuclear radiation was discovered in 1896, when Henry Becquerel and Marie Curie discovered that salts of uranium emitted radiation that could be detected with photographic plates. In the 125 years since this discovery, mankind deciphered the structure of the atom and its nucleus, learned how to produce artificial radioactive isotopes (Irène Joliot-Curie and Frédéric Joliot in 1934), discovered how to fission certain heavy isotopes (Otto Hahn, Fritz Strassmann, Lise Meitner and Robert Frisch, 1938/39) and learned how to establish a fission chain reaction (Leo Szilard, Enrico Fermi et al., 1942) and developed numerous applications of nuclear radiation and nuclear energy. The feasibility of releasing nuclear energy by fusing nuclei of light isotopes was postulated already in 1920 (Arthur Eddington) who speculated that such nuclear reactions provide the enormous energy released in the sun and stars. Although research of harnessing nuclear fusion for controlled generation of nuclear energy is being pursued since the late 1940s, mankind has not yet succeeded in producing sufficiently more energy from fusion reactions than the energy invested in inducing these reactions. Additional information on the history and fundamentals of harnessing nuclear energy can be found in (Norman, 2021).

Encyclopedia scope

The Encyclopedia of Nuclear Energy (The Encyclopedia) provides a comprehensive authoritative coverage of a wide range of topics related to the generation, utilization and safe handling of nuclear energy, nuclear radiation and associated technologies, for the benefit of mankind and planet Earth. It covers past developments, the present status, and research and development of advanced innovative technologies that may enable improvements in the generation and utilization of nuclear energy (including nuclear radiation). The Encyclopedia consists of 272 thematic articles written by experts and arranged in 13 Sections; each Section covers the subject area identified in Table 1.

The fundamental concept of this encyclopedia is to provide all this vast and very diversified information in convenient to read cross-referenced articles within a single publication. Each article provides an effective solid foundation of its topic and references for readers interested in deeper exploration of the subject matter.

Table 1 Encyclopedia sections, number of articles per section and the section editors.

Sec. #	Section title (# of articles)	Section editor	Section editor affiliation
1	Fundamentals and history of development of nuclear energy (17)	Eric B. Norman	Professor in the Graduate School, Nuclear Engineering Department, University of California at Berkeley
2	Commercial nuclear power reactors and their design (22)	Russell E. Stachowski	Chief Consulting Engineer, Global Nuclear Fuel
3	Advanced nuclear reactor concepts under R&D (28)	Alexander Stanculescu	Retired Generation Four International Forum Technical Director; Retired Idaho National Laboratory Division Director
4	Safety, regulation, and decommissioning of commercial nuclear power reactors (24)	Joy L. Rempe	Rempe and Associates, LLC
5	Fuel cycle front-end: from mining through utilization (17)	Douglas C. Crawford	Director, Transient Reactor Test Facility, Idaho National Laboratory.
		Colby B. Jensen	National Technical Lead for Fuel Safety Research, Idaho National Laboratory
6	Fuel Cycle back-end: from recycling to deep geological disposal (19)	Christophe Poinssot	Deputy General Director (CEO) and Scientific Director of the French Geological Survey (BRGM) ^a
7	Radiation protection (21)	Laurence Miller	Professor Emeritus, Department of Nuclear Engineering, the University of Tennessee
8	Non-electric applications of nuclear energy (15)	Shannon M. Bragg-Sittou	Lead for Integrated Energy Systems, Idaho National Laboratory ^b
9	Nuclear power for space (16)	David I. Poston	Chief Reactor Designer, Los Alamos National Laboratory
10	Research reactors (23)	Sean O'Kelly	Associate Laboratory Director, Idaho National Laboratory. Chair of IAEA Technical Working Group on Research Reactors
11	Medical, industrial and agricultural applications of nuclear technology (26)	Alan E. Waltar	Retired Professor and Head, Department of Nuclear Engineering, Texas A&M University, College Station
12	Nuclear fusion R&D (26)	David J. Campbell	Munich, Germany. Former Director for Science and Operations, ITER Organization
13	Social issues of nuclear energy (18)	Andrew C. Kadak	Kadak Associates, Inc. Former Professor of the Practice Massachusetts Institute of Technology

^aAlso: Prof. of Nuclear Chemistry at the National Institute of Nuclear Science and technology (INSTN).

^balso National Technical Director for the DOE-NE Integrated Energy Systems program.

Intended readership

The articles are written at a level that users, with a bachelor degree in engineering, scientific and medical disciplines, especially in nuclear engineering, will find understandable and helpful. The Encyclopedia is intended to be an invaluable resource for students and will make an important contribution to the preservation of the vast amount of knowhow developed since the dawn of the nuclear era in the nuclear energy related fields and to its transfer to the new generation.

The Encyclopedia will also be very useful to industry and academia researchers and practitioners in the many scientific and engineering fields related to the generation and use of nuclear energy, including nuclear radiation. It will enable researchers and practitioners to refresh their memory in their field of specialization or expand their knowhow on less familiar subject areas.

The Encyclopedia will also be useful to members of the public with education in engineering or sciences who are interested in learning about specific nuclear energy or nuclear radiation related topics without having to struggle with textbooks or journal articles.

On the need for this Encyclopedia

The publication of this Encyclopedia is very timely for a number of reasons, including the following:

- Nuclear energy can play a very important role in drastically reducing the amount of fossil fuels burned for generation of electricity and, hence, the amount of greenhouse gas (GHG; primarily CO₂) emissions while, at the same time, making more electricity available for developing countries and for supporting the expected growth in the world population. Moreover, nuclear energy can make an important contribution to drastically reducing the amount of GHG emission from the transportation, industrial, residential and agricultural sectors of the economy. Hence, nuclear energy can make a vital contribution to meet the goal set by the 2015 Paris Agreement on climate change and ratified by many nations—to limit global warming to well below 2, preferably to 1.5 degrees Celsius, compared to pre-industrial levels. This point is elaborated upon below in the section: “On the Importance of Nuclear Energy in Avoiding Climate Change Catastrophe”. The state of the art in nuclear energy generation is covered in (Stachowski, 2021; Crawford, 2021).

- The Generation IV (GEN-IV) International Forum (GIF) was created in 2001 as a co-operative international endeavor of research, development, demonstration and deployment of advanced fourth generation innovative nuclear reactors that, hopefully, will be available for commercial deployment by 2030. The objectives of the innovative GEN-IV nuclear energy systems include improved sustainability, economics, safety and reliability, as well as proliferation resistance and physical protection. This encyclopedia provides an update on the state of the GEN-IV R&D efforts and explains the benefits the innovative GEN-IV reactors may provide. The Encyclopedia also describes (Stanculescu, 2021) the advanced nuclear fuel cycles that offer highly improved resource utilization, greatly reduced nuclear waste, and reduced proliferation risks.
- Over the past decade or so, there has been a surge in the number of private companies, mostly supported by venture capital, that are developing advanced innovative Small Modular Reactors (SMRs); reactors designed to generate between 10 to 300 MW of electricity per unit (Stanculescu, 2021). The SMRs offer a new paradigm in the generation and delivery of nuclear power; they promise to improve all aspects of design, engineering, construction and operation of commercial nuclear power plants, including enhanced safety performance, better economic affordability, and reduced financial risk. The components (modules) of SMRs are to be of a standard design, shop fabricated in assembly lines subjected to high quality control, and then transported as complete modules to the power plant site for rapid installation. The SMRs also offer flexible power generation for a wider range of users and applications—central power stations can consist of multiple units installed at a rate that best matches the growth in power demand; alternatively, a single SMR unit can be installed in the vicinity of the power customer using a so-called distributed (localized) power grid. It is even being proposed that the hundreds of shuttered coal power plant sites could be repurposed for SMRs. This encyclopedia describes (Stanculescu, 2021) a sample of the SMRs under development and explains the incentives for their development and the benefits they offer. The Encyclopedia also describes the motivation for, and examples of, so called “microreactors”—reactors producing an electrical power of less than 10 MW. Such reactors are primarily intended for deployment in remote areas which are not connected to the grid and to which the transport of fossil fuel is very expensive, as well as to provide reliable power to sensitive installations even in case of failure of the central power grid.
- The very ambitious space explorations being planned by leading industrial countries cannot succeed without nuclear energy. Space Fission Power (SFP) systems offer the potential to enable truly ambitious exploration of outer space, and ultimately a permanent human presence in space. Most of the benefits of SFP is tied to the very high amount of energy that can be extracted per unit weight of fissile material, which can allow high powers and/or long lifetime at a relatively low mass. SFP systems also offer great flexibility in terms of being able to operate in diverse environments, including environments with no or limited solar radiation, and the ability to provide abundant electrical power and heat from kilowatts to megawatts. Applications of SFP include propulsion and/or power for spaceships, electricity and heat for exploration rovers for landing on Mars (other planets and moons) or for human colonies on the Moon or Mars. This encyclopedia describes (Poston, 2021; Bennett, 2021) the many benefits nuclear energy offers to space exploration and the many challenges that need to be overcome.
- Controlled thermonuclear fusion is the focus of major international research programs that aim to demonstrate the scientific and technological feasibility of large-scale generation of nuclear energy by the fusion of light atomic nuclei. The widely distributed fusion fuel resources together with the favorable anticipated safety and environmental characteristics of future fusion power plants provide a significant motivation for the continued development of the challenging science and technology towards the exploitation of fusion energy for the benefit of mankind. In addition to the description of the fundamental elements of the fusion process and of the principal approaches to the controlled and sustained generation of fusion energy being pursued, this Encyclopedia presents the state-of-the-art for fusion research and development and the progress towards commercial fusion energy generation (Campbell, 2021). The advantages and challenges of nuclear fusion as an energy source are summarized.
- This encyclopedia also describes the many ways nuclear radiation can be harnessed to provide enormous benefits in the fields of medicine, agriculture, modern industry, environmental protection, and public safety (Waltar, 2021). Described in the Encyclopedia are more than a dozen unique properties of radiation technology that allow for these benefits to be achieved. Even though enormous and widespread, the benefits to society from these technologies are largely unknown and unappreciated. The global markets for these technologies exceed USA \$500 billion annually and are growing rapidly.
- Also provided in this Encyclopedia is information on dozens of research reactors (O’Kelly, 2021) that are operating or under construction around the world and provide unique research capability for scientists pursuing advanced research in physics, chemistry, biology, material and other sciences. Another invaluable utilization of research reactors is the production of special radioactive isotopes for numerous applications in medical, industrial and agricultural applications, and scientific research. Some research reactors are also used for demonstrating the performance of evolutionary as well as advanced nuclear fuels and of advanced nuclear power reactor components.
- Public perception of nuclear energy varies from country to country. It tends to be most negative in wealthy democracies like Germany, Australia, and Japan. Contributing to the negative perception is a fear of reactor accidents, a fear of nuclear radiation, a fear of long-lived radioactive waste, and a fear of the nuclear technology misuse for weapons proliferation. The encyclopedia addresses these concerns and provides authoritative objective information that, hopefully, will contribute to dispelling the public misconceptions (Kadak, 2021).
- The Encyclopedia describes measures implemented to ensure the health and safety of the public from nuclear power (Rempe, 2021). These measures evolved as new lessons were learned from operating experience and unplanned events, in particular events with core damage and radionuclide release (including in Three Mile Island, Chernobyl, and Fukushima). Clearly, the

experience gained from the design, evaluation, operation, decommissioning, and regulation of nuclear power plants has led to significant safety improvements. Future advanced reactor designs are expected to incorporate innovative inherent safety features (Stanculescu, 2021).

- The encyclopedia provides a detailed description of the biological effects of nuclear radiation, of how we reliably measure radiation levels and ensure that they do not exceed the permissible levels (Miller, 2021). The Encyclopedia describes the theory and practice of radiation protection that provide the basis for regulatory requirements that are essential for the safe and beneficial use of the many advanced technologies that involve exposure to nuclear radiation. The Encyclopedia explains that everyone is exposed to natural background radiation on a daily basis; that radiation is routinely in use for diagnostics of health conditions, such as for dental and medical X-rays, and that this is the largest source of radiation exposure for almost all human population in developed countries and that the benefits from these practices far exceed their risk. The regulatory permissible level of nuclear radiation is harmless much like a moderate exposure to sunshine is harmless (and may even be beneficial, whereas over-exposure can cause sunburns). In other words, the regulatory limits of doses induced by exposure to nuclear radiation are already substantively protective, and there is no evidence of health improvements by reducing the doses below these limits. Insisting to reduce radiation exposure to as low as possible below the regulatory limits may result in harm.
- Also provided in this Encyclopedia is detailed information about the nuclear waste and how it can be disposed of safely (Poinssot, 2021; Kadak, 2021). Using advanced fuel cycles (Stanculescu, 2021; Poinssot, 2021) the amount and activity of the long-lived nuclear waste can be reduced to few percent of the amount that needs to be disposed of per unit of energy generated using the contemporary “once-through” fuel cycle.

On the importance of nuclear energy in avoiding climate change catastrophe

The world’s population is expected to grow from current ~6.7 billion people to over 9 billion by 2050. As recognized in the United Nations Resolution 70/1 “Transforming our world: the 2030 Agenda for Sustainable Development” (Stanculescu, 2021; United Nations, 2015), providing “universal access to affordable, reliable and sustainable energy” and in particular to reliable electrical energy, is central to human development, social stability and even world peace. Currently, about 2.8 billion people are still lacking modern energy services (International Energy Agency, 2017), and more than one billion do not have access to electricity. Not only the growth of worldwide population, but also the economic growth in developing countries will lead to a continuing increase in the demand for energy.

The tremendous increase in energy generation required for the benefit of the global population has to be accomplished while reducing the rate of GHG (primarily CO₂) emission. Already, “human activities are estimated to have caused approximately 1.0 °C of global warming above pre-industrial levels” according to the Intergovernmental Panel on Climate Change (IPCC, 2018). In order to limit the global temperature increase to around 1.5 °C, total CO₂ emissions need to be reduced to net zero by around 2050.

Germany, for example, had decided to achieve this goal by installing renewable energy generators made of solar photovoltaic panels and wind turbines. Germany also decided to close down its nuclear power plants. As a result, according to Goldstein et al. (2019), “Germany, which went all-in for renewables, has seen little reduction in carbon emissions, and, according to our calculations, at Germany’s rate of adding clean energy relative to gross domestic product, it would take the world more than a century to decarbonize, even if the country wasn’t also retiring nuclear plants early. A few lucky countries with abundant hydroelectricity, like Norway and New Zealand, have decarbonized their electric grids, but their success cannot be scaled up elsewhere; the world’s best hydro sites are already dammed.”

Goldstein et al. (2019) are also saying “we actually have proven models for rapid decarbonization with economic and energy growth: France and Sweden. They decarbonized their grids decades ago and now emit less than a tenth of the world average of carbon dioxide per kilowatt-hour. They remain among the world’s most pleasant places to live and enjoy much cheaper electricity than Germany to boot. They did this with nuclear power. And they did it fast, taking advantage of nuclear power’s intense concentration of energy per unit weight of fuel. France replaced almost all of its fossil-fueled electricity with nuclear power nationwide in just 15 years; Sweden, in about 20 years. In fact, most of the fastest additions of clean electricity historically are countries rolling out nuclear power.”

In the words of World Nuclear Association Director General Agneta Rising in 2019 (Bisconti, 2021): “The 445 nuclear reactors in 30 countries are the low-carbon backbone of electricity systems, operating in the background, day in day out, often out of sight and out of mind, capable of generating an immense amount of clean power. They are the silent giants upon which we rely today.” Table 2 lists the fraction of electricity generated during 2018 in selected countries and globally from energy sources that do not emit greenhouse gases (Pioro et al., 2021). According to Poinssot and Bourg (2021), nuclear energy is within the top three of the most environmental-friendly energy sources; in the same range as hydropower and wind-power. Measured by CO₂ emissions, nuclear energy is even the most environmentally friendly energy source.

It is being suggested (Conca, 2021) that recent research has revealed the potential for extracting practically unlimited supplies of uranium from the oceans at a cost that may come close to that of land mining. If successful, this may make fission nuclear energy practically as renewable as wind and solar (Conca, 2021).

It is not sufficient to decarbonize the electricity generation sector. In the U.S., for example, 33% of CO₂ emissions are attributed to energy generated to support the electricity sector but an additional 36% of emissions result from transportation and 19% result

Table 2 Fraction of electricity generated by clean energy technologies in selected countries.

Country	Nuclear	Renewable	HYDRO
France	72	3	11
Ukraine	53.5	0.7	4.2
Sweden	41	10.2	39
UK	25	25	-
Korea	23.4	0	1.3
Russia	19.0	0	17
USA	19.7	10.9	6.6
Germany	11.6	22.2	-
World	10.2	6.6	16.3

from industrial processes (Bragg-Sitton and Boardman, 2021). There will be no global environmental benefits from switching transportation to use all electric vehicles if the electricity used for charging the batteries is generated in fossil fuel power plants (without sequestration of the CO₂ these plants emit). The realization of the above-mentioned facts is recently leading to a paradigm shift in the approach to the use of nuclear energy that is likely to bring about a restructuring in the entire energy market.

**Fig. 1** Illustrative examples of the near-term integration of existing LWRs with various industry applications (Bragg-Sitton and Boardman, 2021).

Fig. 2 Conceptualized coordination of energy generation sources and demand to maximize flexibility and economic performance while ensuring grid reliability and resilience.

Most energy experts around the world are advocating the development of a portfolio of low-carbon multi-energy technologies including, in addition to hydro-power plants (with very limited potential for expansion in capacity) and the currently favored “renewable” electricity generators, nuclear power plants. Because the power output of the renewable generators greatly fluctuates over the day and over the year, these generators need to be supplemented by effective energy storage devices that significantly add to the cost of energy.

Nuclear power plants, on the other hand, can generate power at a constant rate throughout the day and the year (excluding a shutdown period of ~1 month for refueling and maintenance once every 18–24 months), practically independent of weather conditions, while requiring a smaller land area per unit energy generated relative to the area required by renewable energy generators.

Moreover, nuclear energy can be generated in the form of high temperature heat (Stanculescu, 2021; Bragg-Sitton and Boardman, 2021) that is the most economical form of energy to store and to use as a backup for the intermittent nature of the renewable energy generators. Therefore, a suitable mix of nuclear and renewables is likely to be the optimal strategy for carbon-free energy generation.

Fig. 1 (Bragg-Sitton and Boardman, 2021) is a simplified illustration of the evolving perception of integrated energy systems using contemporary nuclear power reactors (primarily Light Water Reactors, LWR) in combination with solar and wind renewable energy generators to provide electricity and heat energy for transportation and many industries including non-grid energy users.

Fig. 2 (Bragg-Sitton et al., 2021) is a simplified conceptual perception of the proposed transition away from the use of contemporary large central nuclear power plants from their traditional electricity-only production mode to their exploitation for the provision of a variety of outputs. Future energy systems that seek to maximize energy utilization, generator profitability, and grid reliability and resilience must necessarily consider all available carbon-free energy sources, using each available resource in a way that maximizes its benefits while minimizing less-desirable attributes. The future energy systems should include advanced nuclear reactors including Gen-IV reactors, SMRs and even microreactors and should use distributed in addition to centralized electricity grids.

In summary, the need to meet the objective of zero net CO₂ emission by 2050 combined with the need to greatly increase the total global energy generation rate is an enormous challenge that can be achieved only by making use of all available clean energy generation technologies including nuclear in addition to solar and wind electricity generators. At the 2021 Earth Day climate summit, U.S. president Biden called (WSJ, 2021) for slashing U.S. greenhouse gas emissions by 2030 by 50%–52% compared with the baseline year of 2005, as he seeks to put America at the forefront of world-wide efforts to combat climate change. According to WSJ (2021), meeting this objective would require dramatically reshaping key sectors of the economy, from energy to transportation to agriculture.

Concluding remarks

This Encyclopedia of Nuclear Energy provides a very comprehensive, up-to-date and authoritative information related to nuclear energy, including nuclear radiation—from the discovery of the structure of the atom and its nucleus; through the discovery of three different ways to extract energy from nuclei (fission of heavy nuclei, fusion of light nuclei and radioactive decay); through the state-of-art of the nuclear industry for energy generation and for exploitation of several nuclear technologies for medical, industrial, agricultural and other applications; to the research and development of innovative nuclear technologies that are expected to further

increase mankind benefits from nuclear energy. The reader can find in the Encyclopedia a wide range of topics ranging from the contribution of nuclear energy to the evolution of the continents and oceans of planet Earth to the enabling of very ambitious space explorations including the provision of electricity and heat to human colonies on the Moon, Mars and beyond. The Encyclopedia explains why it is essential to greatly increase the nuclear energy generation rate in order to prevent a global warming catastrophe and, at the same time, provide sufficient energy to the growing world population and to the billions of people in underdeveloped countries.

It is hoped that this Encyclopedia will make an important contribution to transferring of the huge amount of technical knowledge accumulated in the field to the young generation, will inspire students to join research and development of innovative nuclear technologies and will contribute to better understanding of the nuclear technologies, their merits and safety by the general public and policy makers. The appreciation of the enormous benefits in the fields of steady reliable clean energy generation, medicine, agriculture, modern industry, environmental protection, and public safety that mankind enjoys every day and which is described in this Encyclopedia will, hopefully, contribute to much greater public acceptance and support of enhanced utilization of nuclear energy in the mix of clean energy technologies.

Acknowledgments

The Editor-in-Chief is very thankful to the Editors of the 13 sections of this encyclopedia who worked very hard and with dedication to compose the scope of their sections, find expert authors for each of their section articles and finally review and revise these articles. Many thanks are also due to the several hundred authors of the encyclopedia articles who agreed to share their expert know-how with the readers. The support provided by the Encyclopedia Content Project Manager Natalie Lovell, by the Associate Content Project Manager, Gayathri S and their staff is highly appreciated.

CONTRIBUTORS TO VOLUME 2

Sherry Adadi

Department of Nuclear Engineering, Texas A&M University, College Station, TX, United States

Nick A Altic

ORAU, Oak Ridge, TN, United States

A Iulian Apostoaiei

Department of Nuclear Engineering, University of Tennessee, Knoxville, TN, United States; and Oak Ridge Center for Risk Analysis, Inc. (ORRISK, Inc.), Oak Ridge, TN, United States

John Arnish

Knoxville, TN, United States

Florence Bart

Department of Dismantling and Waste Conditioning, Energy Division, CEA French Atomic Commission, Marcoule Center, Bagnols-Sur-Cèze, France

Lewis R Blackburn

NucleUS Immobilisation Science Laboratory, Department of Materials Science and Engineering, University of Sheffield, Sheffield, United Kingdom

V Blet

CEA, Marcoule, France

Dennis C Bley

Buttonwood Consulting, Inc., Albuquerque, NM, United States

Bernard Boullis

CEA, Saclay, France

S Bourg

CEA, DES, ISEC, DMRC, University of Montpellier, Montpellier, France

Stéphane Bourg

Commissariat à l'énergie atomique et aux énergies alternatives, Institut des sciences et technologies pour une économie circulaire des énergies bas carbone, CEA Marcoule, Bagnols sur Cèze, France

Douglas G Bowen

Oak Ridge National Laboratory, Oak Ridge, TN, United States

Jordi Bruno

Amphos 21 Group, Barcelona, Spain

Thomas Byrne

Radiation Oncology Department, Cumberland Medical Center, Crossville, TN, United States

Xiangzhou Cai

Shanghai Institute of Applied Physics, Chinese Academy of Sciences, Shanghai, China

Paul Cantownine

Core and Fuel Engineering, Global Nuclear Fuel – Americas, Wilmington, NC, United States

Guoping Cao

Idaho National Laboratory, Originating Organization C420, Idaho Falls, ID, United States

Albert Casagrande

Computational Mechanics and Materials, Idaho National Laboratory, Idaho Falls, ID, United States

Christine Chabert

CEA-Cadarache, Saint-Paul-lez-Durance, France

James I Cole

Idaho National Laboratory, Idaho Falls, ID, United States

James L Conca

UFA Ventures, Inc., Richland, WA, United States

Douglas C Crawford

Idaho National Laboratory, Idaho Falls, ID, United States

Shaheen Azim Dewji

Department of Nuclear Engineering, Texas A&M University, College Station, TX, United States

Donald A Dube

Risk Consultant, Unionville, CT, United States

Keith F Eckerman
Oak Ridge National Laboratory, Oak Ridge, TN, United States

Rodney C Ewing
Geological Sciences, Center for International Security and Cooperation, Stanford University, Stanford, CA, United States

Karl N Fleming
KNF Consulting Services LLC, Spokane, WA, United States

Guy L Fredrickson
Idaho National Laboratory, Originating Organization C420, Idaho Falls, ID, United States

Ruchi Gakhar
Idaho National Laboratory, Originating Organization C420, Idaho Falls, ID, United States

Laura J Gardner
NucleUS Immobilisation Science Laboratory, Department of Materials Science and Engineering, University of Sheffield, Sheffield, United Kingdom

RO Gauntt
Gauntt Technical Safety Associates, LLC, Edgewood, NM, United States

Tyler J Gerczak
Particle Fuel Forms Group, Oak Ridge National Laboratory, Oak Ridge, TN, United States

Stéphane Gin
Department of Dismantling and Waste Conditioning, Energy Division, CEA French Atomic Commission, Marcoule Center, Bagnols-Sur-Cèze, France; and Long Term Behavior Laboratory, Bagnols-sur-Cèze Cedex, France

J-P Glatz
Retired from European Commission, Joint Research Centre, Karlsruhe, Germany

Bernd Grambow
Subatech, IMT-Atlantique, CNRS, University of Nantes, Nantes, France

Alexandra C Hackett
Oak Ridge National Laboratory, Oak Ridge, TN, United States

Nils H Haneklaus
Danube University Krems, Krems an der Donau, Austria; and Freiberg University of Mining and Technology, Freiberg, Germany

TW Hansen, Jr
Ameriphsics LLC, Knoxville, TN, United States

Lawrence Heilbronn
Nuclear Engineering Department, University of Tennessee, Knoxville, TN, United States

Grant W Helmreich
Oak Ridge National Laboratory, Oak Ridge, TN, United States

Patrick Hogan
Idaho National Laboratory, Idaho Falls, ID, United States

Ian Hore-Lacy
World Nuclear Association, Blackburn North, VIC, Australia

Michael Howard
Department of Nuclear Engineering, University of Tennessee, Knoxville, TN, United States

John D Hunn
Oak Ridge National Laboratory, Oak Ridge, TN, United States

Neil C Hyatt
NucleUS Immobilisation Science Laboratory, Department of Materials Science and Engineering, University of Sheffield, Sheffield, United Kingdom

Wade P Ivey
Oak Ridge National Laboratory, Oak Ridge, TN, United States

Colby B Jensen
Idaho National Laboratory, Idaho Falls, ID, United States

Warren F Jones
Idaho National Laboratory, Idaho Falls, ID, United States

Jan-Fong Jue
Idaho National Laboratory, Idaho Falls, ID, United States

Toni Karlsson
Idaho National Laboratory, Originating Organization C420, Idaho Falls, ID, United States

Masato Kato
Fuel Cycle Design Department, Japan Atomic Energy Agency, Ibaraki, Japan

Dennis D Keiser, Jr
Idaho National Laboratory, Idaho Falls, ID, United States

John H Kessler
J Kessler and Associates, LLC, Charlotte, NC, United States

Inn Seock Kim
ISSA Technology, Inc., Germantown, MD, United States

David A King
ORAU, Oak Ridge, TN, United States

David C Kocher
Oak Ridge Center for Risk Analysis, Inc., Oak Ridge, TN, United States

Robert Lutz
Lutz Nuclear Consulting, Hendersonville, NC, United States

Marty Malsch
Egan, Fitzpatrick Malsch and Lawrence PLLC, Washington, DC, United States; and Egan, Fitzpatrick, Malsch & Lawrence PLLC, Washington, DC, United States

Craig M Marianno
Texas A&M University, College Station, TX, United States

Jean-Michel Marin
Recycling Business Unit, Orano, Paris, France

Christopher Matthews
Materials Science and Technology, Los Alamos National Laboratory, Los Alamos, NM, United States

Rod McCullum
Organization Nuclear Energy Institute, Washington, DC, United States

Soufiane Mekki
ANDRA—French National Radioactive Waste Management Agency, Administrator of IAEA and OECD/NEA relations with Andra, International Relations Department, Chatenay-Malabry cedex, France

Daniel S Metlay
Institute for International Science and Technology Policy, George Washington University, Washington, DC, United States; and B. John Garrick Institute of Risk Sciences, University of California, Los Angeles, CA, United States

Mitchell K Meyer
Idaho National Laboratory, Idaho Falls, ID, United States

Manuel Miguiriditchian
CEA, DES, ISEC, DMRC, University of Montpellier, Marcoule, France

Laurence Miller
Department of Nuclear Engineering, The University of Tennessee, Knoxville, TN, United States; and

Department of Nuclear Engineering, University of Tennessee, Knoxville, TN, United States

Shinya Mizokami
TEPCO Holdings Company, Tokyo, Japan

Mohammad Modarres
University of Maryland, College Park, MD, United States

Glenn A Moore
Walsh Engineering Services, Idaho Falls, ID, United States

Trent L Nichols
Department of Nuclear Engineering, Nuclear Engineering Building, The University of Tennessee, Knoxville, TN, United States

Stephen Novascone
Computational Mechanics and Materials, Idaho National Laboratory, Idaho Falls, ID, United States

Hakan Ozaltun
Idaho National Laboratory, Idaho Falls, ID, United States

Sulgiye Park
Geological Sciences, Center for International Security and Cooperation, Stanford University, Stanford, CA, United States

Giovanni Pastore
Department of Nuclear Engineering, University of Tennessee, Knoxville, TN, United States; and Computational Mechanics and Materials Department, Idaho National Laboratory, Idaho Falls, ID, United States

Sylvain Peugot
Department of Dismantling and Waste Conditioning, Energy Division, CEA French Atomic Commission, Marcoule Center, Bagnols-sur-Cèze, France; and Highly Radioactive Material Laboratory, Bagnols-sur-Cèze Cedex, France

Ronald Pevey
Nuclear Engineering Department, University of Tennessee, Knoxville, TN, United States

William C Phillips
Idaho National Laboratory, Originating Organization C420, Idaho Falls, ID, United States

Ch Poinssot
BRGM, French Geological Survey, Orléans, France

Christophe Poinssot
French Geological Survey (BRGM), Orléans, France

Douglas L Porter

Idaho National Laboratory, Idaho Falls, ID, United States

Barry Rabin

Idaho National Laboratory, Idaho Falls, ID, United States

Bob Rand

Global Nuclear Fuel – Americas, Wilmington, NC, United States

Harold B Ray

Public Utility Executive Vice President, Chief Nuclear Officer (Retired), San Marino, CA, United States

Joy L Rempe

Rempe and Associates, LLC, Idaho Falls, ID, United States

Céline Roussel

ORANO group, Montigny-le-Bretonneux, France

Gérald Senentz

Orano, Châtillon, France

Alexander R Sich

Department of Physics, Kennesaw State University, Marietta, GA, United States

Vikram Singh

Department of Nuclear Engineering, University of Tennessee, Knoxville, TN, United States

Gordon R Skillman

Skillman Technical Resources, Inc., Hershey, PA, United States

Lisa M Snapp

Y-12 National Security Complex, Oak Ridge, TN, United States

Robin Taylor

National Nuclear Laboratory, Central Laboratory, Sellafield, Seascale, United Kingdom; and National Nuclear Laboratory, Central Laboratory, Sellafield, United Kingdom

Aysenur Toptan

Computational Mechanics and Materials, Idaho National Laboratory, Idaho Falls, ID, United States

Ken G Veinot

Y-12 National Security Complex, Oak Ridge, TN, United States

Timothy J Vitkus

Oak Ridge Associated Universities (ORAU), Oak Ridge, TN, United States; and ORAU, Oak Ridge, TN, United States

Samuel A Walling

NucleUS Immobilisation Science Laboratory, Department of Materials Science and Engineering, University of Sheffield, Sheffield, United Kingdom

Zhiguang Wang

Institute of Modern Physics, Chinese Academy of Sciences, Lanzhou, China

Alexander M Wheeler

Department of Nuclear Engineering, University of Tennessee, Knoxville, TN, United States

Laurence G Williams

Computational Mechanics and Materials, Idaho National Laboratory, Idaho Falls, ID, United States

CONTENTS OF ALL VOLUMES

<i>Editorial Board</i>	<i>v</i>
<i>Editor-In-Chief</i>	<i>vii</i>
<i>Introduction to the Encyclopedia of Nuclear Energy</i>	<i>ix</i>
<i>Contributors to Volume 2</i>	<i>xvii</i>

VOLUME 1

Fundamentals and History of Development of Nuclear Energy

Introduction to Fundamentals and History of Development of Nuclear Energy <i>Eric B Norman</i>	1
What Is the Universe Made of? <i>Alejandro Garcia</i>	3
Discovery of Radioactivity <i>Daniel E DiGregorio</i>	9
Discovery of the Quantum Structure of Atoms and Their Nuclei <i>Kenneth S Krane</i>	19
Origins of Nuclear Energy <i>Jim Napolitano</i>	29
Radioactive Decay <i>E Previtali</i>	35
Nuclear Fission I <i>Jennifer L Klay</i>	45
Nuclear Fission II <i>Andrew E Stuchbery</i>	53
Fissile and Fertile Fuels <i>Jennifer Shusterman</i>	66
Manhattan Project <i>B Cameron Reed</i>	78

Nuclear Fusion <i>Edward C Morse</i>	92
Atomic and Hydrogen Bombs <i>Jim Napolitano</i>	101
Phenomenology of Neutron Interactions <i>Fred E Wietfeldt</i>	107
Phenomenology of Gamma Ray and Charged Particles Interactions <i>Reina Maruyama</i>	117
Radiation Sources <i>David K Wehe</i>	125
Experimental Tools I: Radiation Detectors <i>Ke Han</i>	133
Experimental Tools II: Particle Accelerators <i>Alejandro Garcia</i>	146
Commercial Nuclear Power Reactors and their Design	
Commercial Nuclear Power Reactors and Their Design—Introduction <i>Russell E Stachowski</i>	153
History of PWR and BWR Development <i>Jeffery A Brown and G Ivan Maldonado</i>	157
Physics of the Fission Chain Reaction in Thermal and Fast Reactors <i>Pavel V Tsvetkov and Russell E Stachowski</i>	172
Principles of Design and Operation of Nuclear Power Reactors <i>David A Hamon</i>	187
Pressurized Water Reactors <i>Jeffery A Brown</i>	196
Boiling Water Reactors <i>David A Hamon</i>	214
Heavy-Water Reactors <i>Eleodor Nichita</i>	236
Commercial Nuclear Power Plant Statistics <i>David A Hamon</i>	252
Pros and Cons of Commercial Reactor Designs Part 1: Current Status of Electricity Generation in the World and Selected Countries <i>I Pioro, RB Duffey, PL Kirillov, and R Pioro</i>	263
Pros and Cons of Commercial Reactor Designs: Part 2—Current Status and Future Trends in the World Nuclear-Power Industry and Technical Considerations of Nuclear-Power Reactors <i>I Pioro, RB Duffey, PL Kirillov, and R Pioro</i>	288
Economics of Nuclear Energy <i>Geoffrey S Rothwell</i>	304

Economic Challenges of Nuclear Energy <i>Geoffrey S Rothwell</i>	317
Fuel Rod, Fuel Assembly, and Reactivity Control Assembly Design <i>Michael Y Young</i>	327
Heat Transfer Systems <i>Karen Vierow Kirkland</i>	345
Instrumentation and Control Systems of Nuclear Power Plants <i>Belle R Upadhyaya and Richard T Wood</i>	373
Reactor Operations <i>Michael Y Young</i>	393
Operational Analysis Methods <i>William Walters</i>	405
Transient Analysis Methods <i>RP Martin</i>	422
Containment <i>Phil Sharpe</i>	439
Design of the Balance of Plant <i>M Arcaro</i>	446
Safety of Nuclear Reactors <i>Nicholas R Brown and Seok Bin Seo</i>	456
Management of the Nuclear Waste – Via Disposition or Transmutation <i>Pavel V Tsvetkov</i>	465
Advanced Nuclear Reactor Concepts Under R&D	
Worldwide Status of Advanced Reactors (GEN IV) Research and Technology Development <i>Alexander Stanculescu</i>	478
Sodium-Cooled Fast Reactors <i>F Heidet</i>	490
The High Temperature Gas-Cooled Reactor <i>Michael A Fütterer, Gerhard Strydom, Hiroyuki Sato, Fu Li, Eric Abonneau, Tim Abram, Mike W Davies, Minwhan Kim, Lyndon Edwards, Ondrej Muransky, Manuel A Pouchon, and Metin Yetisir</i>	512
Lead Cooled Fast Reactors <i>Alessandro Alemberti</i>	523
Gas Cooled Fast Reactor System (GFR) <i>Branislav Hatala</i>	545
Molten Salt Reactors <i>Victor V Ignatiev</i>	553
Super-Critical Water-Cooled Reactor (SCWR) <i>Yanping Huang, Jinguang Zang, and Laurence Kim-Hung Leung</i>	569
Advanced Light Water-Cooled Reactor Concepts <i>Eugene Shwageraus</i>	582

Fluoride-Salt-Cooled High-Temperature Reactors <i>Massimiliano Fratoni</i>	602
Introduction to Breed and Burn Reactors <i>Staffan Qvist</i>	609
Molten Chloride Fast Reactors (MCFRs) <i>Jiri Krepel and Kevin J Kramer</i>	625
Traveling Wave Reactor (TWR [®]) <i>Pavel Hejzlar</i>	643
CANDLE Reactor Concept <i>Hiroshi Sekimoto</i>	657
A Seed-Driven Breed-and-Burn Blanket Core Concept <i>E Greenspan</i>	673
Worldwide Status of Small Reactors Research and Technology Development <i>Frederik Reitsma and M Hadid Subki</i>	685
Water Cooled Small Modular Reactors (Integral PWR and BWR) <i>M Hadid Subki</i>	694
Floating Nuclear Power Plants With Small Modular Reactors <i>M Hadid Subki</i>	711
Pebble Bed Gas Cooled Reactors <i>Frederik Reitsma</i>	721
Heavy Liquid Metal (HLM) Cooled Fast Small Modular Reactors <i>Craig F Smith</i>	732
Micro-Reactors <i>Janne Wallenius</i>	749
Light Water Reactors (LWR) Fuel Cycle Options <i>Eugene Shwageraus</i>	757
Advanced Fuel Cycles Identification and Evaluation <i>R Wigeland, T Taiwo, M Todosow, W Halsey, and J Gehin</i>	771
Self-Sustaining Breeding in Advanced Reactors: Characterization of Natural Resources <i>Jiri Krepel</i>	786
Self-Sustaining Breeding in Advanced Reactors: Characterization of Selected Reactors <i>Jiri Krepel and Evzen Losa</i>	801
Self-Sustaining Breeding in Advanced Reactors: Comparison of Fuel Cycle Performance <i>Jiri Krepel</i>	820
Advanced Modeling and Simulation Methods <i>Carlo Fiorina</i>	837
Additive Manufacturing in the Nuclear Reactor Industry <i>Benjamin R Betzler</i>	851
New Reactor Concepts Deployment Challenges and Opportunities <i>Ramesh Sadhankar</i>	864

VOLUME 2

Safety, Licensing and Decommissioning of Power Reactors

Safety, Regulation, and Decommissioning of Commercial Nuclear Power Reactors—Introduction <i>Joy L Rempe</i>	1
Safety Lessons From Two Events Without Core Damage <i>Joy L Rempe</i>	6
The Three Mile Island Unit 2 Accident <i>Gordon R Skillman and Joy L Rempe</i>	17
The Chernobyl Nuclear Power Plant Unit-4 Accident <i>Alexander R Sich</i>	30
The Events at Fukushima Daiichi <i>Shinya Mizokami and Joy L Rempe</i>	53
Ensuring Safety by Design and Evaluation <i>Joy L Rempe</i>	67
Reactor Protection System <i>Robert Lutz and Bill Williamson</i>	76
Engineered Safety Features <i>Robert Lutz and Bill Williamson</i>	88
Instrumentation and Control <i>Robert Lutz and Bill Williamson</i>	99
Guidance for Operating Within Design Basis Conditions <i>Robert Lutz and Bill Williamson</i>	108
Beyond Design Basis Event Considerations <i>Robert Lutz and Bill Williamson</i>	115
Safety Evaluations <i>RO Gauntt</i>	126
Overview of Nuclear Regulation and Regulatory Framework <i>Joy L Rempe and Laurence G Williams</i>	139
U.S. Regulation and Licensing—Historical Perspective <i>Dennis C Bley and Marty Malsch</i>	150
U.S. Regulations for Commercial Nuclear Power Plants <i>Dennis C Bley and Marty Malsch</i>	163
U.S. Options for Licensing a New Commercial Power Plant <i>Harold B Ray</i>	168
Regulation of Two U.S. Non-LWRs—Lessons Learned <i>Joy L Rempe</i>	175
Overview of International Nuclear Safety Regulation and Licensing <i>Laurence G Williams</i>	188
Probabilistic Risk Assessment <i>Mohammad Modarres and Inn Seock Kim</i>	207

Regulatory Applications of Risk Assessment <i>Donald A Dube</i>	218
Risk Assessment Insights and Impact <i>Karl N Fleming</i>	227
Nuclear Power Plant Decommissioning <i>Rod McCullum</i>	240
SAFSTOR Decommissioning Example (Kewaunee) <i>Rod McCullum</i>	247
DECON Decommissioning Example (Maine Yankee) <i>Rod McCullum</i>	251
The Nuclear Fuel and Fuel Cycle	
Introduction to Fuel Cycle Front End: From Mining Through Utilization <i>Douglas C Crawford</i>	255
Uranium Resources <i>Ian Hore-Lacy</i>	265
Uranium Extraction From Seawater Makes Nuclear Power Virtually Renewable <i>James L Conca</i>	277
Unconventional Uranium Resources From Phosphates <i>Nils H Haneklaus</i>	286
Uranium Conversion and Enrichment <i>Patrick Hogan</i>	292
Fuel Design and Fabrication: Pellet-Type Fuel <i>Masato Kato</i>	298
Fuel Design and Fabrication: Fast-Reactor Metal Fuels <i>Douglas L Porter and Douglas C Crawford</i>	308
Fuel Design and Fabrication: TRISO Particle Fuel <i>Grant W Helmreich and John D Hunn</i>	318
Fuel Design and Fabrication: Research Reactor Fuel <i>James I Cole, Jan-Fong Jue, and Glenn A Moore</i>	326
Nuclear Criticality Safety <i>Douglas G Bowen</i>	334
Fresh Fuel Properties: Ceramic Compounds <i>Giovanni Pastore and Aysenur Toptan</i>	343
Zr-Alloyed Metallic Fuel Properties <i>Stephen Novascone, Christopher Matthews, Albert Casagrande, Aysenur Toptan, and Adam Zabriskie</i>	356
Molten Salt Fuels: Properties, Purification, and Corrosion Control <i>Ruchi Gakhar, William C Phillips, Guoping Cao, Tae-Sic Yoo, Michael E Woods, Guy L Fredrickson, and Toni Karlsson</i>	366
Irradiation Performance: Light Water Reactor Fuels <i>Paul Cantownine and Bob Rand</i>	377

Irradiation Performance: Fast Reactor Fuels <i>Colby B Jensen and Nicolas E Woolstenhulme</i>	392
Irradiation Performance: High-Temperature Gas Reactor Fuels <i>Tyler J Gerczak</i>	407
Irradiation Performance: Research Reactor Fuels <i>James I Cole, Hakan Ozaltun, Jan-Fong Jue, Warren F Jones, Dennis D Keiser, Jr, Barry Rabin, and Mitchell K Meyer</i>	420
The Nuclear Waste and its Disposal	
Key Characteristics of Used Nuclear Fuel <i>J-P Glatz</i>	429
Fuel Storage (New Fuel/Used Fuel Pool) <i>John H Kessler</i>	441
The Chemical Basis for Separating Recycling Materials by Hydro-Processes <i>Robin Taylor</i>	450
The Chemical Basis for Separating Recycling Materials by Pyro-Processes <i>Stéphane Bourg</i>	465
The Current Industrial Mono-Recycling of U and Pu: Reprocessing Step <i>Gérald Senentz</i>	482
The Current Industrial Mono-Recycling of U and Pu: Recycling Step <i>Jean-Michel Marin</i>	494
Routes for Pu Multi-recycling <i>Bernard Boullis and Christine Chabert</i>	510
The Adaptation of Recycling Processes to Pu-Multi Recycling <i>Manuel Miguiritchian and Robin Taylor</i>	523
Effluent Decontamination <i>V Blet</i>	534
ILW conditioning and performance <i>Samuel A Walling, Laura J Gardner, and Neil C Hyatt</i>	548
HLW Conditioning and Long-Term Performance <i>Florence Bart, Christophe Poinssot, Stéphane Gin, Sylvain Peuget, and Céline Roussel</i>	564
Spent nuclear fuel long term behavior and performance <i>Bernd Grambow</i>	577
The Concept of Geological Disposal of Highly Radioactive Nuclear Waste <i>Rodney C Ewing and Sulgiye Park</i>	588
Radionuclide Migration in the Context of High-Level Nuclear Waste Management <i>Jordi Bruno</i>	603
Main Repository Projects Worldwide <i>Soufiane Mekki</i>	616
Actinide Immobilization in Dedicated Wasteforms: An Alternative Pathway for the Long-Term Management of Existing Actinide Stockpiles <i>Lewis R Blackburn and Neil C Hyatt</i>	650

Potential Fuel Cycle Back-End for Thorium Fuel Cycle <i>Xiangzhou Cai and Zhiguang Wang</i>	663
Assessment of the Relative Environmental Footprint of Nuclear Energy and Its Fuel Cycle <i>Ch Poinssot and S Bourg</i>	675
Social Acceptability of Geologic Disposal <i>Daniel S Metlay</i>	684
Radiation Protection	
Radiation Protection – Introduction <i>Laurence Miller</i>	698
Ionizing Radiation: Discovery and Dose Quantities <i>Shaheen Azim Dewji</i>	701
Fundamentals of Health Physics <i>Shaheen Azim Dewji and Laurence Miller</i>	716
Natural and Man-Made Sources of Radiation <i>Laurence Miller, A Iulian Apostoaei, Michael Howard, and Vikram Singh</i>	744
Source Terms for Nuclear Reactors Operations, Accidents, and Waste <i>Vikram Singh and Alexander M Wheeler</i>	765
External Dosimetry <i>Ken G Veinot</i>	777
Internal Dosimetry <i>Lisa M Snapp and Keith F Eckerman</i>	790
Instrumentation and Practices for Radiological Assessments <i>Timothy J Vitkus, David A King, Nick A Altic, and Wade P Ivey</i>	803
Emergency Response <i>Craig M Marianno</i>	828
Standards to Control Radiation Exposures of Workers and the Public <i>David C. Kocher</i>	840
Risk Tradeoff Analysis <i>TW Hansen, Jr</i>	851
Computer Codes for Determining Acceptable Levels of Contamination <i>John Arnish</i>	858
Characterization and Release of Contaminated Sites <i>Timothy J Vitkus</i>	869
Radiological Control Practices <i>TW Hansen, Jr</i>	890
Radiation Shielding Methods <i>Ronald Pevey</i>	899
Shielding Against Galactic and Solar Radiation in Space <i>Lawrence Heilbronn</i>	914
Health Effects and Radiation Biology <i>Trent L Nichols and Thomas Byrne</i>	923

Estimation of Health Risks From Exposure to Ionizing Radiation <i>A Iulian Apostoaei</i>	937
Drones for Radiological Assessment <i>Alexandra C Hackett</i>	950
An Illustrative Example of Microdosimetry—Boron Neutron Capture Therapy for Cancer <i>Trent L Nichols</i>	958
Radiation Protection: Glossary of Terms <i>Shaheen Azim Dewji, David C Kocher, and Sherry Adadi</i>	981

VOLUME 3

Non-Electric Applications of Terrestrial Nuclear Reactors

Introduction to Nonelectric Applications of Nuclear Energy <i>Shannon M Bragg-Sitton and Richard D Boardman</i>	1
District Heating and Nuclear Power <i>AE Schweikert and MR Deinert</i>	8
Nuclear Driven Water Desalination <i>Aaron S Epiney, Konor L Frick, Cristian Rabiti, Jeffrey Brown, and Shannon M Bragg-Sitton</i>	17
Nuclear-Supported Electrification of the Transportation Sector <i>Xinyu Liu, Adarsh Bafana, Pingping Sun, and Amgad Elgowainy</i>	25
Heat Pumps Driven by Zero-Carbon Electricity <i>J Stephen Herring</i>	34
Coupling Heat Storage to Base-Load Nuclear Reactors for Variable Heat, Electricity and Hydrogen <i>Charles W Forsberg</i>	40
Process Heat for Chemical Industry <i>Richard D Boardman, Michael G McKellar, Brian D Dold, Andrew W Foss, and Haydn C Bryan</i>	49
Industrial Processes for Grid Stabilization <i>Frédéric Bienvenu</i>	61
Thermochemical Hydrogen Production <i>Sellathurai(Sam) Suppiah</i>	73
High Temperature Steam Electrolysis <i>Richard D Boardman</i>	82
Synthetic Hydrocarbon Fuels From H ₂ and Captured CO ₂ <i>Lesley Snowden-Swan, Shuyun Li, Jeromy Jenks, Steven Phillips, Jalal Askander, Jamie Holladay, L Todd Knighton, and Daniel S Wendt</i>	94
Ammonia Synthesis <i>Richard D Boardman</i>	113
Hydrogen-Based Flash Ironmaking Technology (HyFIT): A Novel Green Ironmaking Technology With Low Energy Consumption <i>Hong Yong Sohn</i>	122

Calcination	131
<i>Nils H Haneklaus</i>	
Marine Propulsion	139
<i>Anil Kumar Anand and J Stephen Herring</i>	
Nuclear Power for Space and Propulsion	
Introduction to Space Nuclear Power and Propulsion	155
<i>Gary L Bennett</i>	
Radioisotope Power: Benefits and Challenges	168
<i>Gary L Bennett</i>	
Radioisotope Power: Historical Review	174
<i>Gary L Bennett</i>	
Radioisotope Power: Technology Options	191
<i>Gary L Bennett</i>	
Space Fission Power: Benefits and Challenges	201
<i>David I Poston</i>	
Space Fission Power: Historical Review	213
<i>Susan S Voss</i>	
Space Fission Power: Technology Options – Reactor Core	223
<i>David I Poston</i>	
Space Fission Power: Technology Options—Heat Transport	237
<i>David I Poston</i>	
Space Fission Power: Technology Options—Radiation Shielding	250
<i>David I Poston</i>	
Space Fission Power: Kilopower and KRUSTY	266
<i>David I Poston</i>	
Nuclear Thermal Propulsion: Benefits and Challenges	280
<i>David I Poston</i>	
The History of Nuclear Thermal Rocket Development	290
<i>Cassandra Graham</i>	
Nuclear Thermal Propulsion: Technology Options	303
<i>David I Poston</i>	
Nuclear Electric Propulsion for Rapid Transportation Within the Solar System	321
<i>Christopher Morrison</i>	
Advanced Propulsion: Pulsed, Fusion, Antimatter and Breakthrough Physics	343
<i>Steven D Howe</i>

Glossary

Criticality The normal operating condition of a reactor, in which nuclear fuel sustains a fission chain reaction. A reactor achieves criticality (and is said to be critical) when each fission event releases a sufficient number of neutrons to sustain an ongoing series of reactions.

Defense-in-depth (DiD) A design and regulatory principle that relies on several consecutive and independent levels of protection that would have to fail before harmful effects could be caused to people or to the environment. If one level of protection or barrier were to fail, the subsequent level or barrier would be available. When properly implemented, DiD ensures no single technical, human or organizational failure could lead to harmful effects and the combinations of failures that could give rise to significant harmful effects are of very low probability.

Design Basis Accident (DBA) One category of postulated accidents used to set criteria and limits for the design and sizing of safety-related structures, systems, and components (SSCs).

Design Basis Event (DBE) An event considered in the range of conditions, including normal operation, DBAs, and natural phenomena, for which the plant must be designed to ensure acceptable performance of SSCs.

Engineered Safety Feature (ESF) A SSC relied upon during or following a DBE to prevent or mitigate the associated consequences from such an event.

Nuclear Facility Regulation The inspection, assessment, permissioning and enforcement activities, which are applied to siting, design, construction, commissioning, operation and decommissioning of nuclear installations, to provide reasonable assurance of adequate protection of public health and safety.

Reactivity A measure expressing the departure of a reactor system from criticality. A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

Regulatory Framework for Nuclear Facilities Relevant regulations, criteria, guidance, standards, or other documents used to regulate nuclear facilities.

Safety Evaluation The study, examination and description of a nuclear installation's expected behavior throughout its life, under normal and transient conditions and under postulated events, in order to determine: (a) safety margins provided in normal operation and in transient regimes; and (b) the adequacy of measures to prevent and mitigate the consequences of accidents that may occur.

Introduction

Nuclear power has unique attributes compared to other energy-producing technologies. These include a relatively high energy density, decay heat production after shutting down the fission chain reaction, and the potential to release radionuclides. These attributes have led to special measures being instituted to ensure the health and safety of the public. These measures evolved as new lessons were learned from operating experience and unplanned events, in particular events with core damage and radionuclide release. Clearly, the experience gained from the design, evaluation, operation, decommissioning, and regulation of nuclear power plants has led to significant safety improvements.

Chapters in this section, “Safety, Regulation, and Decommissioning of Commercial Nuclear Power Reactors”, focus on the safety, regulation, and decommissioning of commercial nuclear power plants. These chapters emphasize five major topic areas: **Unplanned Events affecting Reactor Safety**; **Ensuring Safety by Design and Evaluation**; **Regulation and Regulatory Framework**; **Probabilistic Risk Assessment**; and **Decommissioning**. Experts with unique knowledge about these topic areas were invited to author these chapters. Authors were encouraged not only to provide factual information but also to present their perspective regarding the significance of past events, on-going activities, and actions to be performed in the future. Although some readers may wish to solely focus on a single topic and chapter, others may wish to explore all chapters pertaining to a particular topic area. To assist the latter readers, this chapter has been included to introduce these topic areas and provide a roadmap of the relationship between chapters within a topic area and other topic areas included in this section. Suggestions to assist the reader in gaining important insights about each topic area are also provided.

Unplanned events affecting reactor safety

As with other facilities that introduce new technologies, nuclear power plants were designed and licensed to minimize the likelihood of accidents that could adversely affect public health and safety. Nevertheless, unplanned events have occurred at commercial nuclear power plants, some with core damage and radionuclide release. Such events provided important lessons and ultimately, led to improvements that enhance the safety of the operating fleet and new designs.

This section includes four chapters describing unplanned events that led to significant safety measures being implemented. [Rempe \(2021a\)](#) describes two highly scrutinized events: the 1975 Browns Ferry fire and the 1983 Salem Anticipated Transient Without Scram (ATWS) events. Although neither event resulted in core damage or radionuclide release, each resulted in important changes to reduce the potential for their reoccurrence at these and other nuclear reactors. The remaining three chapters review severe accidents that resulted in core damage at: Three Mile Island Unit 2 ([Skillman and Rempe, 2021](#)), Chernobyl Nuclear Power Plant Unit 4 ([Sich, 2021](#)), and Fukushima Daiichi Units 1, 2, and 3 ([Mizokami and Rempe, 2021](#)). Substantial efforts were, or in some cases continue to be, completed by the regulator and industry to understand the progression, root causes, and lessons associated with each event. These efforts have also resulted in important measures being required to prevent and mitigate such events and improve reactor safety.

As emphasized with these and other chapters within this section (see **Ensuring safety by design and evaluation** and **Regulations and regulatory framework**), unplanned events resulted in modifications to existing plant structures, systems, and components (SSCs) as well as changes to the methods used to evaluate SSC performance. Significant safety lessons were learned and continue to be discovered from events with and without core damage. Many of these lessons are independent of the reactor technology and country in which the event occurred. In identifying these lessons, it is important to understand the root causes of these events. There are similarities in the root causes, such as inadequate procedures for operation and maintenance, insufficient operator training, design deficiencies, regulatory deficiencies, and inadequate safety culture. Likewise, there are similarities in the types of lessons learned and the types of changes implemented to address these lessons. Although significant advances have been implemented to improve reactor safety, the industry must continue to remain vigilant in identifying safety lessons and taking appropriate corrective actions.

Ensuring safety by design and evaluation

Nuclear power plant safety is assured by maintaining three key safety functions: control reactivity, control cooling, and control radioactivity release. These key safety functions, often referred to as “Critical Safety Functions” are ensured by various measures, such as inherent and passive safety features, multiple independent barriers, engineered safety systems, instrumentation for plant monitoring, and procedures and guidance for operators. A Defense-in-Depth (DiD) principle is used to ensure these safety functions are maintained for a range of challenges and operating conditions. This principle, which is enforced by a regulatory framework, is applied in reactor design and evaluation activities.

This section includes seven chapters emphasizing how critical safety functions are maintained by ensuring appropriate plant SSCs are selected. [Rempe \(2021b\)](#) provides an overview of this area, highlighting interactions between efforts to achieve critical safety functions, apply the DiD principle, and develop an appropriate regulatory framework. Chapters are also provided that describe representative Reactor Protection Systems ([Lutz and Williamson, 2021a](#)), Engineered Safety Features ([Lutz and Williamson, 2021b](#)), and Instrumentation and Control Systems ([Lutz and Williamson, 2021c](#)) found in U.S. Pressurized Water Reactors (PWRs) and Boiling Water Reactors (BWRs). These reactor systems are selected considering the following objectives: maintain critical safety functions, address safety principles such as DiD, and adhere to regulatory requirements and guidance. [Lutz and Williamson \(2021d,e\)](#) call attention to the importance of guidance provided to operators for operational and beyond design basis events. This guidance is also essential in assuring that critical safety functions are maintained. [Gauntt \(2021\)](#) provides an overview of analyses required for evaluating the performance of plant systems, operator actions, and measures to prevent and mitigate accident release. These analyses are used to demonstrate compliance with regulatory requirements and in some cases, to modify the regulatory framework.

Several chapters emphasize prior events that occurred at operating nuclear power plants, such as the events described in **Unplanned events affecting reactor safety**, and landmark analysis efforts, such as major PRAs described in **Probabilistic risk assessment**. These events and analysis efforts influenced system designs, guidance, and regulation. Requirements for plant design and evaluations have evolved and continue to evolve as new insights are gained from operating experience.

Regulation and regulatory framework

Society demands governments regulate industrial applications that present potential harm to people or the environment. The amount of regulatory oversight should be commensurate with the magnitude and likelihood of the potential hazard. The application of nuclear energy for commercial power production is no exception; because of the high hazard potential, it is subject to a stringent nuclear regulatory framework. Although licensing and regulation of nuclear facilities is, in general, a national responsibility, severe accidents with core damage and radiation release reinforce the international aspects associated with commercial nuclear power applications.

This section includes five chapters focussing on reactor regulation. [Rempe and Williams \(2021\)](#) provides an overview of nuclear reactor regulation and regulatory frameworks, highlighting key concepts associated with effective regulation and the objectives, requirements, scope, roles, functions, and attributes of an effective regulatory body. Because of its lead in deployment and regulation of commercial nuclear power plants, four chapters emphasize the U.S. experience with commercial reactor regulation, which evolved over time. [Bley and Malsch \(2021a\)](#) provides a historical review of the evolution of the U.S. licensing process. Current requirements found within U.S. regulation that affect commercial power reactor operation are reviewed in [Bley and Malsch \(2021b\)](#). [Bley and Malsch \(2021a,b\)](#) highlight factors that led to significant changes in the current U.S. Nuclear Regulatory Commission (NRC) regulatory framework. [Ray \(2021\)](#) describes the two licensing pathways currently provided by the NRC to allow operation of a commercial nuclear power plant, identifying the advantages and disadvantages of each pathway. In recent years, there has been renewed interest in advanced reactor systems with different fuels, materials, and coolants than found in current generation Light Water Reactor (LWR) systems. [Rempe \(2021c\)](#) provides insights gained from prior experience with two first-of-a-kind non-LWRs (a gas-cooled reactor and a sodium-cooled fast reactor) authorized for startup by the predecessor of the NRC, the U.S. Atomic Energy Commission. Insights emphasize the importance of factors, such as prior operating experience from similar plants, an appropriate regulatory framework with review and oversight by an independent regulator, initial testing and operation, and complexity and technology advances. As described by [Bley and Malsch \(2021a\)](#) and [Fleming \(2021\)](#), recent actions are being taken by the NRC to establish an optional new regulatory framework to address issues identified in these two and other non-LWR licensing activities. As this new process is explored, it is important to consider difficulties encountered during prior non-LWR licensing, startup, operating, and decommissioning activities. In recognition that operation of commercial nuclear power plants has the potential to transcend borders, international guidance has been developed to outline expectations for assuring public health and safety. [Williams \(2021\)](#) provides an overview of this international guidance and compares regulatory frameworks found in several countries with significant nuclear power programs. Despite differences in legal systems and cultures, these descriptions indicate each country provides nuclear safety regulation and licensing consistent with international expectations.

Together, these chapters emphasize desirable attributes of a regulator and a regulatory framework, the principles of effective regulation, and consequences when regulatory frameworks possessing the desired attributes are not in place. Within this section, several chapters (see **Unplanned events affecting reactor safety**) identify factors, such as the lack of an independent regulator and the need for an adequate regulatory framework, as root causes of unplanned events.

Probabilistic risk assessment

Probabilistic Risk Assessment (PRA) provides a systematic method for answering three questions:

- What can go wrong?
- How likely it is?
- What its consequences might be?

Risk assessments results identify expected outcomes of accident sequences, sensitivities in analysis results, areas of importance, plant system interactions, and areas of uncertainty in plant response. PRAs have been performed to gain important insights about operating reactors as well as new reactor concepts in various phases of design, licensing, and construction. Appropriate delineation of accident sequences, as well as accurate quantification of their frequencies, consequences, and associated uncertainties, is essential for deriving these insights; and appropriate use of these insights separates PRA from deterministic approaches to reactor safety. Risk-informed decision-making, using PRA insights, has been increasingly applied to assess plant safety, enhance plant design, improve operations, optimize maintenance, and optimize resources. In addition, these insights have been used to establish regulatory requirements that better focus licensee and regulator attention on design and operational issues commensurate with their importance to public health and safety.

This section includes three chapters on the topic of PRA. [Modarres and Kim \(2021\)](#) describes the basic concepts associated with risk assessment and presents the overall process used to perform a nuclear power plant PRA. [Dube \(2021\)](#) highlights several

examples in which the NRC has effectively used a “risk-informed approach” in regulatory decision-making and oversight. Fleming (2021) provides several examples of risk insights derived from early PRAs and describes how these insights have been and continue to be used to support risk-informed decision making for existing plants and advanced reactors, including a recent effort to select licensing basis events and design requirements.

Of special interest in these chapters are descriptions of risk metrics and importance measures as well as methods used to derive risk insights and support risk-informed decision-making. To avoid misleading conclusions, however, it is important to understand the limitations of PRAs and associated risk metrics and importance measures. Prior risk assessments have significantly influenced reactor design, operation, and regulation (see chapters in *Ensuring safety by design and evaluation* and *Regulation and regulatory framework*).

Decommissioning

Unlike other industrial facilities, a nuclear power plant requires an owner plan for the facility’s entire life cycle, including decommissioning, prior to receiving an operating license. In the U.S., the NRC requires plant owners establish and maintain a trust fund or another financial mechanism to ensure coverage of all costs for the ultimate decommissioning of the facility. Although some countries initially lacked the strong regulatory governance for decommissioning funding that exists in the U.S., it is now common worldwide to require that plant owners provide financial assurance for the plant’s entire life cycle.

This section includes three chapters related to the topic of decommissioning. McCullum (2021a) presents an overview of U.S. and international decommissioning strategies, regulatory requirements, status, and practices. Currently, there are three strategies through which decommissioning is accomplished—SAFSTOR, DECOM, and ENTOMB. These three strategies are described, and details are provided about activities conducted within each strategy. U.S. nuclear plants that have completed, are undergoing, or are soon to enter the decommissioning process are identified. McCullum (2021b) and McCullum (2021c) provide examples of two U.S. plants that followed two of the more commonly used strategies, SAFESTOR and DECON. These examples illustrate how additional aspects associated with decommissioning, such as public involvement and public policy, influence the ultimate land use of the site.

Information within these chapters demonstrates that initial plans required and overseen by the regulator are being implemented to complete decommissioning successfully. It is also of interest to note that efforts are underway to complete decommissioning within shorter timeframes and at lower costs.

Summary

This section focuses on the safety, regulation, and decommissioning of commercial nuclear power plants. Chapters within this section emphasize the following topic areas: Unplanned Events affecting Reactor Safety, Ensuring Safety by Design and Evaluation, Regulation and Regulatory Framework, PRA, and Decommissioning. As described within these chapters, the experience gained from the design, evaluation, operation, regulation, and decommissioning of nuclear power plants led to significant safety improvements. This introductory chapter provides the reader with a roadmap for this section; special insights are highlighted from each topic area.

Acknowledgments

As the author of this chapter and the editor for this section, I wish to acknowledge the contributions provided by authors of chapters within this section. As noted in *Introduction*, these individuals have unique knowledge regarding information they discussed. Their willingness to share their expertise is greatly appreciated. In addition, I wish to acknowledge the encouragement, guidance, and reviews provided by Professor Ehud Greenspan, Editor-in-Chief of the *Encyclopedia of Nuclear Energy*, and the support and patience of the Elsevier editorial staff.

Glossary

Advisory Committee on Reactor Safeguards (ACRS) Independent advisory committee to the U.S. Nuclear Regulatory Commission that is statutorily mandated by the Atomic Energy Act of 1954, as amended.

Anticipated Transient An event expected to occur one or more times during the life of a nuclear power plant.

Anticipated Transient Without SCRAM (ATWS) An anticipated operational occurrence involving a failure of the reactor trip portion of the reactor protection system. If not mitigated, the event could result in reactor fuel melting.

Backfitting Modification of or addition to systems, structures, components, or design of a facility, commonly understood to be required by regulatory direction.

Common Cause Failure (CCF) The simultaneous failure or unavailability of more than one similar or identical component due to an underlying common cause.

Reactor Protection System (RPS) System designed to monitor key plant variables to detect off-normal plant conditions arising from anticipated transients and to automatically initiate whatever safety action is needed.

Reactor Trip System (RTS) Critical portion of the RPS that includes the power sources, sensors, initiation circuits, logic matrices, bypasses, interlocks, racks, panels, control boards, actuation devices, and actuated devices, required to initiate reactor shutdown.

SCRAM or Trip A manual or automatic command to insert control rods with the intention of shutting down a nuclear reactor by immediate termination of the fission chain reaction.

Introduction

At the time when nuclear plants were deployed for commercial power production, there was strong awareness about potential hazards associated with the release of radioactive materials. As with other industries that introduce new technologies, nuclear power plants were designed and licensed to minimize the likelihood of accidents that could adversely affect public health and safety. As described in [Rempe and Williams \(2021\)](#), defense-in-depth measures, such as remote siting, containment buildings, and engineered safety features, were implemented to compensate for this lack of experience. Unplanned events led additional safety measures to be implemented.

In Section 4, “Safety, Regulation, and Decommissioning of Commercial Nuclear Power Reactors”, three chapters are devoted to descriptions of reactor accidents that resulted in core damage at nuclear power plants: Three Mile Island Unit 2 ([Skillman and Rempe, 2021](#)), Chernobyl Nuclear Power Plant Unit 4 ([Sich, 2021](#)), and Fukushima Daiichi Units 1, 2, and 3 ([Mizokami and Rempe, 2021](#)). Significant safety lessons were and continue to be gained from these events.

This chapter describes two highly scrutinized events that resulted in no core damage: the 1975 Browns Ferry fire based on information provided in ([TVA, 1975](#); [US NRC, 1976](#); [Haskin et al., 2002](#); [Okrent, 1981](#); [Scott, 1976](#); [Williamson, 2016](#)) and the 1983 Salem Anticipated Transient Without SCRAM (ATWS) events based on information provided in ([Haskin et al., 2002](#); [Okrent, 1981](#); [US NRC, 2008](#); [INPO, 1980](#)). Although there were no adverse effects to public health and safety, important measures were implemented to reduce the potential for reoccurrence of such events and to enhance the safety of operating commercial nuclear reactors.

1975 Browns Ferry fire

On March 22, 1975, a major fire burned for 7 h at the Tennessee Valley Authority Browns Ferry Nuclear Plant (BFNP) located near Decatur, Alabama. The fire and its aftermath revealed several significant inadequacies in design and procedures related to fires at that plant. Some equipment did not function correctly. Furthermore, some response actions were either incorrect or not as effective as they should have been. The fire caused extensive damage to electric power and control systems, impeded the function of normal and standby cooling systems, and degraded the capability to monitor the plant status. The reactors were shut down and cooled successfully. No one on site was seriously injured, and there was no radiological impact on the public. Post-event evaluations, however, identified many safety lessons. Important changes were implemented by the plant owner, the regulator, and the industry.

Background

Historical information

Fire had been recognized as a potential safety concern of importance for at least a decade before the 1975 Browns Ferry fire occurred ([Okrent, 1981](#)), but there were large differences in opinion concerning what measures were needed to make the probability of a serious accident from fires acceptably low. The significant fires that occurred at the San Onofre and Indian Point plants led to some requirement modifications. Evolutionary improvements were implemented into LWRs under construction, and an industry standard was developed. However, these measures were later deemed inadequate.

BFNP

The BFNP included three boiling water reactors (BWRs) designed by General Electric. Each unit was a BWR/4 design with an original licensed thermal power of 3293 MWt and housed in a Mark I containment (see [Fig. 1](#)). Unit 1 was issued its initial operating license in 1973, and Unit 2 was issued its initial operating license in 1974. At the time of the event, Units 1 and 2 were at 100% power and Unit 3 was under construction.

The BFNP is designed such that air flows toward areas of possible higher radiation. Hence, the BFNP reactor buildings and a shared refueling floor are maintained at a negative pressure to ensure that airflow is inward. As part of efforts to connect the Unit 3 reactor building, tests were required to ensure this negative pressure could be maintained. This testing indicated that Unit 1 reactor building air-in-leakage should be reduced, and an extensive program was underway for resealing.

Units 1 and 2 share a common control room with a cable spreading room located beneath the control room. Electrical cables between the control room and plant equipment pass through the cable spreading room. The cable-tray penetrations through the reactor building walls of each reactor were sealed to minimize in-leakage. This was accomplished by filling a penetration with a polyurethane foam to form a seal, and then applying a 3–6 mm layer of flameproofing compound over the foam and over the cables on both sides of the penetration (for 30 cm) to form a fire barrier. Additional cables had been pulled through some of the penetrations after they were originally installed. In order to make an opening for these cables, holes were punched through the sealant and flameproofing materials.

To check the effectiveness of penetration sealing, it was commonplace to hold a lit candle near the penetration opening. If the opening was not fully sealed, the lower pressure in the reactor building would cause air (and the candle flame) to be pulled through the opening, providing visual indication of leakage. Two days earlier, minor fires had occurred at BFNP due to the use of candles for leak testing. In these cases, however, workers were able to quickly extinguish the fire without any damage.

Fig. 1 Layout of BFNP Unit 1. Adapted from Haskin FE, Camp AL, Hodge SA, and Powers DA (2002). *Perspectives on Reactor Safety*. NUREG/CR-6042, Rev 2 March 2002. ML021080026. Graphic found on page 1.6-8 (page 102/333 of pdf).

Event sequence

Tables 1 and 2 summarize the sequence of events that occurred on March 22, 1975. During the early stages of the fire, operators were too busy to log events and actions. Hence, some of the listed times, which were established by reviewing available data and interviewing plant staff, differ in the cited references.

Table 1 Timing of events on March 22, 1975 associated with BFNP cable spreading room fire. Based upon information in (TVA, 1975; US NRC, 1976; Williamson et al., 2016; Haskin et al., 2002).

Time	Event
~12:20	Fire started in penetration.
~12:20–12:30	Portable CO ₂ and dry chemical fire extinguishers discharged into the hole.
~12:30	Two construction workers leave spreading room for Unit 1 reactor building to fight the fire.
~12:35	Plant fire alarm sounded. Fire logged by the Shift Engineer. ^a
~12:35–12:45	CO ₂ alarm sounded in spreading room; permanently installed spreading room CO ₂ (Cardox) system, which had been isolated because of leak repair activities, was discharged.
~12:37	Portable dry chemical fire extinguisher discharged in reactor building.
~12:40	Alarms sound in the control room; smoke from wiring under control panel observed.
~12:40–13:10	Spreading room CO ₂ system operated second time.
~12:40–13:00	Assistant Shift Engineer ^a assumes direction of fire brigade in fighting fire.
~15:00	Spreading room CO ₂ system operated third time.
~15:00	Shift Engineer assumes charge of spreading room firefighting.
~16:20	Spreading room fire extinguished (primarily using dry chemicals).

^aAt that time, a Shift Engineer was a senior reactor operator serving in the position that is today known as the Shift Manager. At that time, an Assistant Shift Engineer was a senior reactor operator serving in the position that is today known as the Unit Supervisor or Control Room Supervisor.

Table 2 Timing of events on March 22, 1975 associated with BFNP reactor building fire. Based upon information in (TVA, 1975; US NRC, 1976; Haskin et al., 2002; Williamson et al., 2016).

Time	Event
~12:30	Two construction workers leave spreading room for Unit 1 reactor building to fight the fire.
~12:37	Portable dry chemical fire extinguisher discharged in reactor building.
~12:40	Assistant Shift Engineer ^a reports exact location of fire in reactor building.
~12:40–13:00	Portable CO ₂ and dry chemical fire extinguishers discharged in the reactor building.
~13:00–13:10	Because smoke was so dense, air-breathing equipment was requested and received within 5 min.
~13:09	Assistant Shift Engineer ^a requested that Athens Fire Department come to the plant.
~13:30	Lighting lost in reactor building.
~16:45	Temporary d.c. lighting installed.
~18:35–19:00	Water applied to fire.
~19:30–19:45	Reactor building fire extinguished.

^aAt that time, a Shift Engineer was a senior reactor operator serving in the position that is today known as the Shift Manager. At that time, an Assistant Shift Engineer was a senior reactor operator serving in the position that is today known as the Unit Supervisor or Control Room Supervisor.

An electrical inspector and an electrician were sealing air leaks in the Unit 1 cable spreading room (see Fig. 1). While one particular penetration was being tested using this open flame technique, a hole (5 × 10 cm) allowed the candle flame to be drawn into the open void where it ignited the foam sealant (~12:20). The fire progression was not stopped by initial attempts, such as beating it with a flashlight, using rags to smother the fire, and discharging CO₂ and dry-chemical fire extinguishers.

The electrician called for someone to notify the reactor operations Shift Engineer that there was a fire in the cable spreading room. Meanwhile, airflow pulled the fire more deeply into the hole until it reached the reactor building side of the wall. At 12:34, the shift engineer was notified there was also a fire in the reactor building. Thus, firefighting activities had to consider two locations: the cable spreading room and the reactor building.

The fire department in Athens, Alabama, was notified and arrived at 13:45. At about 14:00, the Fire Chief recommended the use of water on the fire. However, the Plant Superintendent rejected this recommendation because of the potential that water could introduce short circuits, adversely impacting equipment to control, shutdown, and cool the reactor. Furthermore, the fire was progressing slowly (2–3 cm/min). The use of CO₂ and dry chemical fire extinguishing systems kept the cable room fire suppressed. On several occasions, the fire was reported to be extinguished, but the high energy content in the cables caused the fire to flare up. The fire in the cable room was finally extinguished at about 16:20.

The fire continued to burn in the reactor building. It was located about 6 m above the floor, making access difficult. Attempts to discharge dry-chemical and CO₂ extinguishers were limited due to workers experiencing difficulties in breathing and poor visibility. When the reactor building ventilation system was lost, excessive smoke reduced visibility and necessitated the use of air-breathing equipment. Eventually, lighting was lost in the reactor building. Air-breathing equipment for workers to fight the fire was limited because such equipment was also required by workers that were manually aligning valves for reactor shutdown cooling.

As noted above, water was not initially used because of reactor safety concerns. Between 18:35 and 19:00, the Plant Superintendent agreed to use water on the fire because the reactor had been shutdown for several hours with several options available for decay heat removal. Then, efforts to use water were initially delayed due to a nozzle from the Athens fire truck not fitting the threads on the hose to the second floor of the reactor building. By 19:45, the fire was declared out.

BFNP response

Although operator actions averted core damage, the plant sustained significant damage during the 7 h the fire burned. Approximately 1600 electrical cables that control Units 1 and 2 were damaged with approximately 630 of these being designated as safety related. The electrical cables, after insulation had been burned off, shorted together and grounded to their supporting trays or to the conduits, with the result that control power was lost for much of the installed equipment such as valves, pumps, and blowers. In Unit 1, all the Emergency Core Cooling System (ECCS) was rendered inoperable and operators lost the ability to monitor power from the control room. Portions of the Unit 2 systems were likewise affected.

Enough equipment remained operational throughout the event to shut down the reactors and maintain the reactor cores in a cooled and safe condition.

Unit 1

At approximately 12:42, the Unit 1 operator noted anomalous behavior of instrumentation and control systems designed to provide emergency cooling of the reactor core. Operators reacted to several events, such as the automatic starting of pumps and equipment associated with the low pressure coolant injection (LPCI), core spray (CS), high pressure coolant injection (HPCI), and reactor core isolation cooling (RCIC) systems. After it was determined these systems weren't needed, this equipment was stopped but automatically restarted. At 12:48, both recirculation pumps automatically reduced their flow outputs, dropping the reactor power level from 100% to 70%.

At 12:51, both recirculation pumps stopped, and the operators manually scrammed the reactor. However, the reactor continued to produce heat from the radioactive decay of fission products. At approximately 12:55, several electrical boards that supplied control voltages and power to many of the systems used to remove decay heat became unavailable. Many of the instruments and indicating lights were also lost due to damaged cables. In addition, smoke was observed coming from beneath the ECCS panel. Shortly after 13:00, the main steam isolation valves (MSIVs) closed automatically, presenting two additional challenges. First, the steam generated by the decay heat could not be transferred to the condenser, eliminating an important heat sink. Second, steam from the core was no longer available to drive the feedwater pumps, eliminating another method of providing high-pressure cooling water to the core. The fire eventually disabled several shutdown cooling systems, including the LPCI, CS, HPCI, and RCIC systems. Even though a control rod drive (CRD) system pump was supplying flow at around 400 L/min, decay heat induced boiling of water within the pressure vessel. Condensate booster pumps were operable, but these pumps can only inject water into the pressure vessel at pressures of 2.4 MPa or less. Given these conditions, the operator depressurized the reactor, which was at 7.4 MPa, to allow the use of available low-pressure systems.

The pressure-relief valves were manually opened from the control room at ~13:20, and the steam was transferred from the pressure vessel to the pressure-suppression pool (see Fig. 1). This method reduced the vessel pressure to about 1.8 MPa in 20 min. During the depressurization, the water level in the core decreased but did not drop below a point 1.2 m above the top of the fuel. Once the reactor pressure was reduced below 2.4 MPa, one condensate booster pump and one condensate pump provided makeup water to restore the water level to its normal height by 13:30. This mode of core cooling was adequate until about 18:00, when loss of control air prevented further manual control of the remaining (4 out of 11) operable pressure relief valves. The valves closed, and pressure in the RPV started to rise. As pressure increased above 2.4 MPa, the condensate booster pumps could no longer inject water into the vessel and thus only the CRD system pump was adding water.

After the fire was declared out at 19:45, the smoke began to clear. After about 3.5 h (~21:50), control of the relief valves was restored, the reactor was depressurized, and the condensate booster pump again pumped water into the reactor. With low-pressure operation now secured, adequate makeup water could be supplied by one of the condensate pumps. Alternate modes of cooling also became available.

Unit 2

The effect of the fire on Unit 2 was less pronounced. Nine minutes after Unit 1 was shut down, Unit 2 operators responded to several abnormal events, such as reactor power decreasing, many alarms sounding, and several indicating lights failing. The reactor was scrammed at 13:00.

The turbine was immediately tripped, along with the reactor feedwater pumps. In approximately 4 min after scram, the MSIVs closed, isolating the reactor steam from the condenser and the reactor feedwater pump steam supply. The RCIC and HPCI systems were immediately initiated to control reactor water level. These two systems tripped several times over the next hour. At approximately 13:45, the HPCI system became unavailable, but the RCIC system continued to supply high pressure water to the reactor.

When the MSIVs closed, the reactor pressure was relieved by manual operation of the relief valves. Manual operation of the relief valves was lost at 13:20. However, the relief valves lifted intermittently on pressure until 14:15. At that time, manual operation was restored, and the reactor was depressurized using the relief valves. At 22:10, the MSIVs were reopened, making the condenser heat sink available. At 22:20, the RHR system could be used for long-term cooling of the reactor.

Safety lessons

Post-event evaluations, such as the one conducted by the Special Review Group established by Executive Director of Operations of the U.S. Nuclear Regulatory Commission (NRC), (US NRC, 1976) emphasized several important safety lessons from the Browns Ferry fire. Reviews emphasized the importance of fire protection measures and common-cause failures that could adversely affect the ability of operators to safely shutdown the reactor and take actions to preclude core damage. In addition, evaluations emphasized the importance of proper maintenance procedures, quality assurance programs, and safety culture. The licensee, the regulator, and the industry have implemented important measures in response to these lessons.

Fire protection

Post-event reviews identified the need for better fire prevention and protection criteria, codes, and standards for nuclear power plants. Revisions were suggested to address topics, such as separation of redundant control circuits and power cables, the use of combustible materials within the plant, the placement of systems and equipment to detect and fight fires, the use of water to extinguish a fire, and adequate reporting procedures.

For example, concerns about shorting circuits that would make the plant more difficult to control and shutdown led the Plant Superintendent to make the conscious decision to not initially use water to extinguish the fire. This position reflected a widespread reluctance on the part of licensees to use water on a fire involving electrical cables. However, failures caused by the fire as it continued to burn were largely responsible for the difficulties encountered by operators as they took actions to restore the plant to a safe and stable condition. The fire was quickly extinguished when water was finally applied. Although the Special Review Group agreed that reactor safety takes precedence over extinguishing a local fire, they recommended that water be considered if initial attempts to extinguish a cable fire with non-water means are unsuccessful. Investigations also identified other issues such as the

existence of the fire not immediately being detected by installed smoke detection systems and the exact location of the fire not being identified when construction workers initially reported the fire.

The Special Review Group urged the NRC staff and industry standards groups to accelerate efforts to develop standards and requirements for instrumentation needed to inform operator actions. Instrumentation that failed or gave erroneous or erratic indications did not result in any incorrect operator actions at BFNP. However, operators had to use indirect and inferred methods to obtain needed information and confirmatory indicators weren't available. For example, the control rod position indicators and on-line radiation monitoring systems became inoperative during the event. The Special Review Group recommended that special attention be given to instrumentation required for operator actions and that additional emphasis be placed on the concept of defining a minimum set of safety equipment.

Common mode failures

Despite the independence and separation criteria applied in the plant's design, damage to electrical power and control circuits resulted in the loss of redundant subsystems and equipment. These failures stemmed from two principal reasons: (1) potential failure sources (e.g., the interconnection of safety equipment and non-safety circuits such as indicator light circuits) were not recognized; and (2) the conduit used to isolate cables from their redundant counterparts did not adequately protect the cables (see Fig. 2). The damage inflicted by the fire resulted in the loss of Unit 1 cooling and depressurization systems (e.g., LPCI, HPCI, CS, RCIC, and the automatic depressurization systems). Although loss of the ECCS was beyond conditions for which the plant was designed, there were numerous diverse alternatives still available to the operators to provide cooling throughout the event. In addition to the Unit 1 CRD pump used during this event, there was also the potential for cooling to have been provided by the standby liquid control system and if actions were taken to allow it to be driven by steam from an auxiliary boiler, the Unit 1 RCIC.

Maintenance work control, quality assurance, and safety culture

Except for notations on design drawings, there were no written procedures or work instructions covering the sealing and testing of penetrations during their original installation or subsequent modifications. For example, the engineering aide with the assigned responsibility to find the air leaks was actually plugging the leaks (instead of the journeyman electrician).

Several references (e.g., Okrent, 1981; TVA, 1975; US NRC, 1976; Williamson, 2016; Lewis, 2010) emphasized that the BFNP fire illustrates a failure of the plant owner to institute adequate quality assurance practices, the staff or industry to develop adequate fire protection codes or regulations, and the regulatory staff to respond to an identified problem. Thus, Okrent (1981) observed that this fire is a perfect example of difficulties associated with the "thorny decision-making process" involved with modifications to equipment, procedures, or practices to an operating plant.

Regulatory actions

The BFNP fire was an important challenge to the NRC which began operation in January 1975. As a result of this fire, the NRC issued Branch Technical Position Paper (BTP) 9.5-1 and Appendix A to BTP 9.5-1 to provide licensees guidance about required fire

Fig. 2 Damage observed from BFNP Cable Spreading Room. Note melted aluminum electrical cable conduit. TVA File Photo published in U.S. Nuclear Regulatory Commission (2009) *The Browns Ferry Nuclear Plant Fire of 1975 and the History of NRC Fire Regulations: DVD*. NUREG/BR-0361, Supplement 1. Available from <https://www.nrc.gov/docs/ML0912/ML091250195.pdf>, accessed September 29, 2019.

protection programs at commercial nuclear power plants. The NRC also required each licensee to conduct a Fire Hazards Analysis (FHA) at each power plant and to respond to the requirements of the BTP. In 1980, the NRC issued fire protection regulation [Appendix R to 10 CFR Part 50 or 10 CFR50.48(b); see (U.S. Government Publishing Office, 2019)], which further codified the minimum levels of fire protection that must be provided by the licensees. Appendix R is a highly prescriptive regulation with which existing nuclear power plants must comply or from which they must request exemptions. It requires physical separation of safe shutdown equipment so that failure of one train would not affect the other train. The industry adopted compensatory fire protection measures to address times when there are non-conformances, such as the use of fire watches during maintenance activities.

The NRC approved the final rule incorporating the use of the National Fire Protection Association (NFPA) Standard 805, Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants 2001 edition (NFPA 805) as 10CFR Part 50.48(c). NFPA 805 allows licensees to use tools such as fire modeling and risk analysis to develop a fire protection program. The NRC has indicated that NFPA 805 can be used as a performance-based method to demonstrate that fire protection safety requirements have been met, subject to certain conditions, rather than compliance with prescriptive Appendix R fire protection requirements.

1983 Salem Unit 1 Anticipated Transient Without SCRAM (ATWS) events

On two occasions (February 22 and 25, 1983), Unit 1 of the Salem Nuclear Generating Station (Salem Unit 1) located near Lower Alloways Creek Township, New Jersey, failed to scram automatically due to failure of both reactor trip breakers (RTBs) to open on receipt of an actuation signal. In both cases, the unit was successfully tripped by manual action. The failure of the breakers was attributed to excessive wear from improper maintenance of the under voltage (UV) relays which receive the trip signal from the protection system and result in the breakers opening mechanically. The Salem Unit 1 events, by themselves, were mild transients, but the potential existed for more serious events. Thus, these events provide several important lessons for improving and assuring the safety of commercial nuclear power plants.

Background

Historical information

Early concerns about ATWS in the commercial fleet were raised in Advisory Committee on Reactor Safeguards discussions with the NRC staff and reactor designers (Okrent, 1981). The primary concern, which related to potential interactions (i.e., common mode failures) between reactor control and protection systems, stemmed from an event that occurred at the High Temperature Reactor Experiment (HTRE-3) (GE, 1959). In this reactor, the control system and the protection system took inputs from the same neutron flux instruments, which did not function as designed due to incorrect installation, ultimately leading to a core damage accident.

In September 1973, the regulatory staff of the Atomic Energy Commission (AEC) documented their position on ATWS in WASH-1270 (US AEC, 1973), stating that separation of control and protection functions should be achieved to a reasonable degree, either by physical separation or by electrical isolation. Design changes necessary to either address the consequences of anticipated transients would vary depending on when an applicant submitted their construction permit application. Earlier submittals would need to demonstrate that consequences were acceptable, while later applications would need to incorporate design changes that improve the reliability of the reactor shutdown systems. Operating plants would be considered on a case-by-case basis. Subsequent evaluations (US NRC, 1978) concluded that corrective measures to reduce the probability or consequences of ATWS events were required because the reliability of current reactor trip systems (RTSs) cannot be shown to be adequate because of the rate at which they were challenged. There was concern that the RTS and other equipment required to function during an ATWS event weren't sufficiently invulnerable to common cause failures. Concerns about ATWS events were exacerbated by failures of reactor scram systems observed within the U.S. and abroad; most notably, an event at Browns Ferry Unit 3 in which 76 of the 185 control rods failed to fully insert in response to operators initiating a manual scram when the reactor was at about 35% power on June 28, 1980 (INPO, 1980; Williamson, 2016; Haskin et al., 2002).

On November 24, 1981, 15 months before the Salem Unit 1 ATWS events, the NRC invited comments on three proposed ATWS rules. Each alternative featured a different approach to reduce the risk from ATWS events. In July 1982, a group of NRC personnel from several offices was formed to consider comments received on the three proposals and to develop a final rule on ATWS. Ultimately, the ATWS Steering Group opted to evaluate generic plants using an approach that defined the various fixes and estimated the reduction in probability for ATWS sequences as each additional requirement was added. This gave a value (a benefit associated with the reduction in risk) that could be compared to the impact (cost in dollars) of each incremental requirement. Although there are large uncertainties in such analyses, they proved useful in evaluating various modifications proposed for resolving ATWS concerns.

Salem Unit 1

The Salem Nuclear Power Plant includes two four-loop pressurized water reactors (PWRs) designed by Westinghouse. Unit 1, which received its initial operating license in 1976, had a rated thermal power of 3133 MWt. On the two dates when the ATWS events occurred (February 22 and 25, 1983), Unit 1 was operating at low power levels and Unit 2 was under construction.

As typical for Westinghouse PWRs, the Salem Unit 1 RTS design uses circuit breakers that open to trip the reactor. During normal operation, the circuit breakers are closed and supply power to the CRD mechanisms. Each reactor trip breaker (RTB) undervoltage

Fig. 3 Salem Unit 1 Reactor Trip Breaker (RTB) design (A) at the time of the event and (B) after modifications were implemented. US Nuclear Regulatory Commission (US NRC) (2008) *0523-R504P-Westinghouse Advanced Technology—04.7—Anticipated Transient Without SCRAM (ATWS)*. ML11216A089, July 2008. Available from <https://www.nrc.gov/docs/ML1121/ML11216A089.pdf>, accessed October 2019 (Images from pages 17 and 19/26 of pdf).

coil is energized and holds the main trip shaft in the position shown in Fig. 3A. When a trip signal is generated, the RPS de-energizes the undervoltage coil and releases the main trip shaft. This allows the trip spring to pull the top portion of the trip bar to the left and opens the RTB. Opening the RTB removes power from the power cabinets and allows the control rods to fall into the core. The undervoltage coil provides a fail-safe feature of the RPS; if a loss of power to the RPS occurs, the undervoltage coils de-energize and the RTBs open. In addition to the undervoltage coil, each RTB has an associated shunt trip coil. Energizing this coil pulls the shunt trip lever down. As this lever moves down, it contacts the main trip shaft and causes a reactor trip. Salem Unit 1 used two redundant RTBs in series to minimize the potential for spurious reactor trips (US NRC, 2008).

Event sequences

At 12:21 on February 25, 1983, a low-low water level condition in one of the four steam generators at Salem Unit 1 initiated a reactor trip signal. At the time, the reactor was at 12% of its rated thermal power in preparation for power escalation after a recently completed refueling outage. Upon receipt of the reactor trip signal, both RTBs failed to open (as noted above, at least one of these circuit breakers was required to open in order for the control rods to drop into the core and trip the reactor). About 25 s later, operators manually initiated a reactor trip from the control room and shutdown the reactor. Following the manual trip, the plant was stabilized in the hot standby condition. All other systems functioned as designed. The cause of the failure to trip was determined to be failure of the UV trip attachment devices to function as designed. The plant was placed in cold shutdown at the request of the NRC.

On February 26, 1983, NRC investigators discovered that a similar failure had occurred in Salem Unit 1 at 09:55 on February 22, 1983. With the reactor at 20% power, operators attempted to transfer the 4160-V group electrical busses from the station power transformers to the auxiliary power transformers; this was routine during power escalation. During the transfer attempt, a limit switch failed, causing the loss of one of the nonvital busses and the immediate loss of associated equipment, including one reactor coolant pump, control power to the operating main feedwater pump, control room lighting, and a 125-Vac miscellaneous distribution panel. At 09:56, a low-low level condition occurred in one steam generator (due to the loss of the main feed pump), initiating a reactor trip signal. Due to the abnormal conditions created by the loss of the 4160-V bus and in anticipation of loss of steam generator water levels, the operator was directed to manually initiate a reactor trip at about the same time. However, it was understood by plant personnel (and reported to the NRC) that the automatic reactor trip signal due to the low-low level in one steam generator had caused the reactor to trip. On February 26, 1983, as a result of NRC queries, a detailed review of the sequence of events in a computer printout for February 22 revealed that the RTBs opened in response to the operator's manual trip signal. Thus, it became evident that on February 22 (as on February 25), the two RTBs failed to open upon receipt of an automatic trip signal from the RPS.

Safety lessons

Because the operators initiated a manual reactor trip shortly after receipt of the automatic trip signals on both February 22 and February 25, no adverse consequences occurred. However, as the first observed ATWS events at a commercial nuclear power plant, the Salem Unit 1 events were of major safety concern. Safety lessons learned from these events emphasize the importance of maintenance, operating procedures, and safety culture.

Post-event testing of the RTBs indicated that both failed because of mechanical binding in the UV trip mechanisms (Thompson, 2016; Marshall, 1983). The breaker failures were attributed to excessive wear from improper maintenance of the UV relays. Root causes included: (1) inadequate attention to the importance of vendor-supplied and NRC-supplied information, (2) absence of an adequate preventive maintenance program, and (3) an inadequate supply, control, and verification of information by the vendor.

While the Salem Unit 1 RTB failures occurred as a result of several possible contributors, evaluations concluded that the predominant cause was excessive wear accelerated by lack of lubrication and improper maintenance. Although other PWRs had experienced RTB failures, none involved an ATWS event.

Regulatory actions

Several NRC actions were initiated in response to these events. One action was plant-specific and addressed before Salem Unit 1 could be restarted. Another was an investigation into the Salem events and the circumstances leading to them. In addition, a task force was formed to study the overall generic implications of this event. Several short-term and long-term actions related to RPS design and testing were taken.

Plant-specific actions

Because of previously identified problems at Salem Unit 1 and the licensee's failure to recognize that an ATWS event had occurred on February 22, 1983, the NRC did not permit restart until technical and management corrective actions were satisfactorily addressed. Detailed reviews of the event and the licensee's corrective actions were performed prior to authorizing restart of Salem Unit 1. As shown in Fig. 3A, the original UV trip attachment design provided only one means by which the RPS would automatically open the RTBs, de-energizing the undervoltage coils. In the aftermath of the Salem events, the RTB device was modified to provide redundant means of automatically opening the breakers. With the modification shown in Fig. 3B, the RPS energizes the shunt trip coil and de-energizes the undervoltage coil for each breaker when the trip logic is satisfied.

On April 26, 1983, the NRC agreed that Salem Unit 1 could be returned to service; however, on May 5, 1983, the NRC forwarded to the Salem licensee a Notice of Violation and Proposed Imposition of Civil Penalties. Violations included operation of the reactor when the RPS could not be considered operable and several significant deficiencies which contributed to the inoperability of the RTBs. An augmented inspection program was instituted to monitor the licensee's progress toward completion of longer-term corrective actions.

Short-term actions

Subsequent initiatives identified and corrected potential deficiencies in RTBs and related maintenance procedures at other plants. Due to the serious nature of these events, the NRC immediately issued Inspection and Enforcement Bulletin No. 83-01 (US NRC, 1983a) to all PWR licensees for action and to other nuclear power reactor facilities for information. IE Bulletins 83-01 and 83-04 (US NRC, 1983a,b) required testing of all circuit breakers in RTSs with an undervoltage trip attachment. IE Information Notice 83-08 (US NRC, 1983c) described the failures of the RTBs discovered in testing and provided recommendations to assure proper operation of RTBs with UV trip attachments being used in other safety-related applications.

In addition, an NRC Task Force was established to determine the generic implications of the Salem Unit 1 events. This work is documented in NUREG-1000 (US NRC, 1983d). As a result, Generic Letter 83-28 (US NRC, 1983e) was issued describing intermediate-term actions to be taken by licensees. The actions address issues related to RTS reliability and general management capability; specifically: (1) post-trip review (the licensee must have adequate procedures, data, and information sources to understand the cause(s) and progression of the trip such that an informed decision on the acceptability of a reactor restart can be made), (2) equipment classification and vendor interface to ensure programs are in place to identify and maintain safety-related components, (3) post-maintenance testing of safety-related equipment, and (4) RTS reliability improvements (US NRC, 1983e).

Long-term impact

The Salem Unit 1 ATWS events contributed to several actions with far reaching effects on the industry (Thompson, 2016). Evaluations of the Salem events were considered in NRC deliberations regarding the 1984 ATWS rule now outlined in 10 CFR 50.62 (U.S. Government Publishing Office, 2019). The Salem events were also considered prior to issuance of Generic Letter 83-28, which directed the industry to establish formal vendor interface programs with an inferred wider scope covering nearly all safety-related equipment. PWRs were required to have equipment that is diverse, reliable, and independent from the RTS to automatically initiate the auxiliary feedwater system and to initiate a turbine trip under conditions indicative of ATWS. BWRs were required to have a diverse recirculation pump trip, alternate rod insertion circuitry, and upgraded emergency operating procedures; or

alternatively, BWRs could have installed high capacity standby liquid control systems. In addition, the staff raised several issues that were closely related to RPS design and testing.

One of the principal findings regarding the Salem Unit 1 ATWS events was the lack of adequate attention being paid to the reliability of the RTS. The Salem Generic Issues Task Force recommended to the Commission that a reliability assurance program be included in the final ATWS rule. While the ATWS rule did not require such a program, the Commission strongly urged the voluntary development of this reliability assurance program. The Commission stressed that ATWS risk reductions can also be achieved by reducing the frequency of transients requiring RPS operation. Challenges to the RPS may arise from unreliable components, inadequate post-trip reviews, poor testing, or tolerance of inadequate or degraded control systems. While not specifically required by the ATWS rule, the Commission urged licensees to analyze challenges to the plant safety systems, particularly the RTS, and determine how improvements could be made. Industry response to this challenge included several major actions (e.g., see Haskin et al., 2002).

The NRC staff in its review of responses to Generic Letter 83-28 approved the installation and operation of the automatic shunt trip in many operating PWRs. As discussed above, the shunt trip attachment was designed to improve the reliability of the circuit breaker, as its function is redundant to the function of the existing UV trip attachment. The staff encouraged each licensee to install the automatic shunt trip at the first refueling following staff review and approval of their design. In addition, the reliability of circuit breakers improved due to more effective maintenance, testing, and inspection programs (Subudhi et al., 1990).

Summary

The 1975 fire in Browns Ferry Nuclear Plant Units 1 and 2 and the 1983 ATWS events at Salem Unit 1 did not result in any adverse effects to public health and safety. However, important safety lessons were gained, and measures were implemented to enhance the safety of the commercial operating fleet. It is important that the industry remain vigilant in identifying safety lessons from future events and in implementing appropriate corrective actions.

Glossary

Core uncover The situation in which the water level within the reactor pressure vessel drops below the top of the fuel elements within a reactor core.

Loss of feedwater In Babcock and Wilcox (B&W) pressurized water reactors (PWRs), a loss of all main feedwater to once-through steam generators.

Pilot operated relief valve (PORV) The power operated relief valve mounted on top of the pressurizer. The PORV is also referred to as the electrometric relief valve.

Severe accident An accident resulting in significant damage to a reactor core with subsequent release of large quantities of radioisotopes beyond the primary coolant system.

Introduction

On March 28, 1979, a loss of feedwater event ultimately led to the first core melt accident in a Pressurized Water Reactor (PWR) deployed for commercial power production. After a brief overview of the plant design, this chapter provides an overview of the accident evolution, activities required for initial stabilization, followed by post-accident analyses and examinations required for long-term stabilization, cleanup, and developing insights. Actions taken to address the insights learned from the TMI 2 accident ultimately increased the safety of the global nuclear enterprise.

TMI 2 design

The Three Mile Island Nuclear Station is a two-unit nuclear power plant located on Three Mile Island in the Susquehanna River, approximately 10 miles southeast of Harrisburg, Pennsylvania (see Fig. 1). Three Mile Island Unit 1 (TMI 1) was licensed to begin operation in 1974 at a rated power of 2535 MWt. Three Mile Island Unit 2 (TMI 2) was licensed to begin operation in 1978 at a rated power of 2772 MWt. TMI 2 had been in commercial operation for less than 90 days when the accident occurred on March 28, 1979.

Fig. 2 Isometric depiction of TMI 2 NSSS showing one of the two CFTs and the RCDT. Courtesy FirstEnergy (current owner/operator of TMI 2 and historical information of TMI 2 images).

Nearly identical to TMI 1, the TMI 2 Nuclear Steam Supply System (NSSS) included a reactor pressure vessel (RPV) with a core containing 177 fuel assemblies, two coolant loops (often designated as Loops A and B), one reactor core drain tank (RCDT), one electrically heated pressurizer, and connecting hot leg, cold leg, and surge line piping. Each coolant loop included a once-through steam generator (OTSG) and two reactor coolant pumps (RCPs). Connected on opposite sides of the RPV, and discharging directly into the RPV downcomer, are the two core flood tanks (CFTs). The pressurizer included one pilot operated relief valve (PORV) and two American Society of Mechanical Engineers (ASME) code-required safety relief valves. The Babcock and Wilcox (B&W) NSSS design is unique in that its Makeup and Purification system includes three identical centrifugal pumps, each serving identical dual functions. These pumps provide normal makeup and RCP seal injection flow as well as High Pressure Injection (HPI)/Emergency Core Cooling (ECCS) flow. The physical configuration and geometric layout of the NSSS are shown in **Figs. 2 and 3**. **Fig. 4** shows the layout of TMI 2 buildings, including the large dry containment (e.g., the reactor building housing the NSSS), the auxiliary building, and the turbine building.

Accident evolution

Plant status

Prior to the accident, TMI 2 was at 97% power with all four reactor coolant pumps (RCPs) operating ([EPRI, 1979](#)). The MU-P-1B pump was in service providing normal makeup and RCP seal injection flow. RCS leakage was approximately 22.7 L/m (6 gpm),

Fig. 3 Isometric showing Coolant Loops A and B of TMI 2 RCS without Core Flood Tanks (CFTs). Rempe JL and Knudson DL (2013) TMI-2—A case study for PWR instrumentation performance during a severe accident. *Idaho National Laboratory Report INL/EXT-13-28043*, p. 16/118.

which was deemed acceptable for TMI 2 at that time. The condensate system was operating with two condensate pumps and two condensate booster pumps in service. Both turbine driven feedpumps were in service. The spray in the pressurizer was operating to equalize the boron concentrations between the pressurizer and the RCS. This equalization was necessary because of steam leakage that was suspected to be from either the relief valve (PORV) or the pressurizer safety valves (ASME valves). This leakage was evidenced by periodic safety valve discharge header temperature alarms. In addition, the plant staff was continuing to perform maintenance on a plugged condensate polisher transfer line and had been doing so for the previous approximately 11 h.

TMI 1 was in hot shutdown for low power physics testing following refueling. There was a vacuum on the condenser, and auxiliary steam was being supplied from TMI 2.

Sequence of events

At approximately 04:00 on March 28, 1979, auxiliary operators were transferring resin from a condensate polisher tank to a resin regeneration tank, encountering difficulty that was attributed to resin blockage in the transfer line. While these operators were clearing the resin blockage, the plant experienced a loss of condensate flow followed by total loss of feedwater to the steam generators. Condensate flow loss was due to the unexpected shutdown of the condensate polisher system pumps in conjunction with a bypass valve failure. Steam generator feedwater was lost because the main feed-water pumps were automatically tripped in response to cutoff of water from the condensate polishers and because flow from the auxiliary feed-water pumps was blocked by two valves that had been inadvertently left closed during prior maintenance. The combined loss of condensate and feedwater flow resulted in the main turbine being tripped at 04:00:37. The emergency feedwater pumps started as designed, and the reactor continued to operate at full power. The PORV opened at its setpoint of 15.5 MPa-g (2255 psig). The reactor tripped when the RCS high pressure trip setpoint of 16.2 MPa-g (2355 psig) was reached.

On reactor trip, coolant in the RCS contracted due to reductions in RCS temperature and pressure. To compensate for RCS coolant contraction, operators took appropriate action to reduce letdown flow and to start a second HPI/Makeup Pump. About 13 s later, the PORV failed to close when RCS pressure decreased to its closure setpoint of 15.2 MPa-g (2205 psig). This was not the first time that a PORV had stuck open. In fact, the same sequence of events occurred in 1977 at a similar B&W plant, Davis-Besse. In that event, an operator recognized that the PORV remained open and immediately blocked it. At TMI 2, this failure of the PORV-to-close was not recognized for about 2 h and 20 min.

About a minute later, the pressurizer water level began to increase. This level increase continued until approximately 6 min after the initiation of the event, at which time the pressurizer level indication went off scale "high" indicating that the pressurizer was completely filled with water or "solid." This was of particular concern to the operators for several reasons. Under normal operating conditions, the pressurizer contains both water and a generous steam cushion that controls RCS pressure, and the steam cushion assures that water is not introduced into the PORV or the ASME valves. Furthermore, because the RCS is filled with water during startup and operation, there is no indication of water level within the core. Operators infer core water level based on the pressurizer water level. Hence, operators were concerned about the pressurizer going "solid" because it impairs their ability to control RCS pressure and they would not be able to prevent primary coolant water from being introduced into the ASME valves and the PORV.

Operators attempted to reduce pressurizer water level by throttling the HPI flow rate and by increasing the letdown flow rate to its maximum value. These efforts were largely unsuccessful. RCS pressure began to increase moderately as the pressurizer went solid; the RCS temperature also increased. The high pressurizer level was caused by voids that formed in the RCS coolant coupled with the open PORV (effectively venting the steam space of the pressurizer to the RCDT and allowing a rapid fluid insurge into the pressurizer).

At approximately 8 min after the start of the accident, an operator discovered that the block valves on the emergency feedwater headers were closed. Upon opening the block valves, the emergency feedwater pumps discharged water into the OTSGs rapidly lowering RCS temperature and associated pressure.

Approximately 14 min after the start of the accident, the rupture disc of the RCDT (see Fig. 2) burst, discharging steam and reactor coolant from the open PORV, combined with original RCDT quench fluid, into the containment.

Reactor coolant mass inventory continued to decrease due to the combination of fluid loss through the open PORV and due to the sustained low coolant injection rate of the throttled HPI system. Although the RCPs continued to operate, their flow rate decreased because conditions were outside their operating limits. The void fraction within the RCS increased to such an extent that it caused cavitation in the RCPs. The operators tripped the RCPs in the B loop at 74 min, and the RCPs in the A loop at 101 min.

When the RCPs in Loops A and B were tripped, the operators expected that natural circulation would initiate. Plant parameters, however, were outside of the operating envelope for natural circulation, and natural circulation did not initiate. Accumulated vapor in upper locations of each loop precluded natural circulation. At this time, RCS pressure continued to decrease but RCS temperature started to increase. Abundant heating due to decay heat generation, combined with the continued unrecognized reactor coolant loss through the PORV and the throttled HPI system flow, contributed to this temperature increase. The throttled HPI flow was considered acceptable by the operators because of the apparently satisfactory, but misunderstood, pressurizer water level.

The RCS pressure decreased to its lowest pressure of 4.6 MPa-g (660 psig) at 2 h and 19 min after the initiation of the accident. At 2 h and 20 min, the operators recognized that the PORV (RC-RV2) was open and proceeded to close its isolation (block) valve, RC-V2. Upon closure of RC-V2, RCS pressure began to increase. This pressure increase was likely caused by heatup from core decay heat and zirconium-water reactor and by additional RCS inventory associated with higher HPI flow rates. The operators believed

that, up to this time, no substantive inventory loss from the RCS had occurred. This belief, however, was also based on the misunderstood pressurizer level without any consideration of the accompanying low RCS pressure.

At approximately 2 1/2 h after the start of the accident, substantial fractions of the reactor core were uncovered and were experiencing sustained high temperatures. These conditions resulted in significant fuel damage, substantial releases of core fission products, and hydrogen generation. The operators recognized neither the magnitude nor extent of these conditions. Additional unsuccessful attempts to establish sustained forced cooling with one or more RCPs were made.

The operators continued unsuccessfully to attempt to collapse the voids in the RCS loops for several hours by opening and closing the PORV block valve, RC-V2, thus relieving the pressure by discharge to the RCDT through the still stuck open PORV. The operators became concerned over the ability of the PORV to remain functional under this high use rate. As a preliminary step for initiating the installed decay heat removal system, the decision was made to reduce the RCS pressure, which would allow water from the CFTs to enter the RCS and assure coverage of the core. This action was largely unsuccessful. Water levels in the CFTs changed only slightly, indicating that only a small amount of CFT fluid entered the reactor vessel. Failure of the CFTs to inject substantial fractions of their fluid volume was interpreted as indication that the core was covered. The CFTs are designed to supply water to the reactor vessel in the event of a large break loss of coolant accident (LOCA) with its accompanying large, rapid depressurization, and for medium sized breaks where CFT fluid injection precedes Low Pressure Injection (LPI). Neither the large and rapid depressurization that accompanies a Large Break LOCA, nor a slower depressurization that accompanies a medium sized break, occurred during the “essentially” small break LOCA associated with TMI 2’s PORV failure to close. Consequently, the CFTs were not effective for core reflood during this scenario.

The extended period of low RCS pressure allowed hydrogen gas, which was generated due to oxidation of zirconium in the fuel cladding, to be released from the RCS. Some of this hydrogen burned in the reactor building at about 10 h after the initiation of the accident producing a rapid pressure spike (at least 0.19 MPa G/28 psig) in the containment. This rapid pressure spike, which was indicated by a single pressure data point, received little attention from most of the plant staff; many were unaware that it had taken place.

Hydrogen release from the RCS may have contributed to the later apparent success of the operators in collapsing the voids in reactor coolant Loop A, to which the pressurizer is connected. This apparent success in establishing what appeared to be some degree of natural circulation in spite of continuing high temperatures in portions of the RCS system likely led the operators to conclude that the RCS had attained stable thermal hydraulic conditions.

In mid afternoon of March 28, 1979, corporate management directed the operators to raise RCS pressure with the objective of collapsing the remaining voids and to start a RCP to establish forced circulation. This was successfully achieved at 1950 h on March 28, 15 h 50 min after the start of the accident.

TMI 2 stabilization

Reactivity management

The as-designed reactor trip on high pressure at approximately 0400 on March 28 resulted in successful insertion of all 61 scrammable control rods ensuring immediate reactor shutdown. Eight axial power shaping rods that were not designed to scram remained in their pre-scram location, 27% withdrawn. No further adjustment of the control rods occurred subsequent to the accident. The normally operating makeup pump MU-P-1B continued to inject water into the RCS injecting from the letdown-storage tank at then current RCS boron concentration levels. The HPI pumps delivered water from the borated water storage tank to the RCS cold legs during their brief use on March 28, injecting several hundreds of gallons of ~2400 ppm borated water into the RCS through nozzles located in the RCS cold legs (Fig. 3). In the weeks after the accident, uncertainty regarding the condition of the core increased. Specifically, uncertainty increased about the core’s geometry, the potential for significant core damage based on the extraordinary radiation levels emerging throughout the plant, and the ability of the control rods to maintain the core subcritical. To address these uncertainties, the RCS boron concentration was first increased to the refueling concentration of 2400 ppm, then, with subsequent intermediate increases, to 6000 ppm.

Long-term cooling

From the afternoon of March 28, 1979, until approximately noon on April 27, 1979, TMI 2 was successfully cooled by manual adjustment of the feedwater flow rate to the Loop A OTSG using a small bypass valve around the main feedwater control valve. Steam created in the Loop A OTSG was drawn to the main condenser by a vacuum through the turbine bypass valve, which was set to control the rate of steaming and hence, the rate of heat removal.

As described by [Elam and Skillman \(1980\)](#), the decision to transition from forced cooling to natural circulation was made in accordance with procedure after the third (and last) pressurizer transmitter failed at 1:07 a.m. on April 27, 1979, approximately 30 days after the initiation of the accident. Approximately 12 h later, the last operating RCP (RC-P-2A) was manually tripped, reducing heat input from the pump into the RCS and resulting in a cool down rate of approximately 6 °C/h (10 °F/h) until a new equilibrium RCS temperature was reached (i.e., when the heat removal rate matched the decay heat generation rate). The transition was made with both steam generators steaming, but the B-Loop OTSG was isolated due to high iodine activity at approximately 1:10 a.m. Thus, the A-Loop OTSG was used exclusively to remove decay heat and promote natural circulation. Prior to this

planned transition to natural circulation, several independent analyses evaluated plant performance. These evaluations concluded that natural circulation would provide adequate capability to remove both decay heat and RCS sensible heat until a long-term decay heat removal system could be installed. Data taken after stopping the last RCS pump confirmed the predicted performance.

RCS pressure control

During the initial hours and days after the accident, RCS pressure was controlled by maintaining a pressurizer steam bubble using the installed electrical heaters (Heater resistance measurements, which were easily accessible because heater distribution panels and circuit breakers were located in the cable spreading room outside the containment, were used to determine that 1100 kW of the 1628 kW of pressurizers heaters were still dependable.) (Elam and Skillman, 1980). Furthermore, reliable pressurizer water level instrumentation, was no longer available. After the transition to natural circulation, the pressurizer was filled with water, and RCS pressure was maintained by adjustment of inflow from the centrifugal makeup pumps. By positioning the letdown valve to balance net in-flow across the normal makeup valve and one of the RCP seal injection valves, RCS pressure was successfully controlled without requiring knowledge of pressurizer water level. This method of pressure control proved to be stable and reliable.

TMI 2 remained in its damaged state from March 29, 1979 until fuel removal began in the fall of 1985. TMI 2 began natural circulation heat removal on April 27, 1979. This method of cooling remained effective first through the steam generators, then through quiescent heat exchange from the reactor vessel to the containment until the last amount of fuel was removed from the reactor vessel years later. Pressure control as described above was effective for the entire duration of natural circulation heat removal and ceased when the RPV head was removed in 1985.

Post-accident damage assessments

Damage assessments, which were required for plant stabilization and cleanup, primarily relied on three sources of information: plant instrumentation data, analysis predictions, and examination observations.

Instrumentation data

Plant data were the primary source of information initially available to operators for assessing the status of TMI 2 and the effects of mitigating actions. The small break LOCA and hydrogen burn events, however, exposed instrumentation to harsh conditions, including direct radiation, radioactive contamination, and high humidity with elevated temperatures and pressures. As discussed in Lutz and Williamson (2021), the TMI 2 accident highlighted the importance of understanding and focusing on key system status information in an environment where operators can be overwhelmed with superfluous and sometimes conflicting data (e.g., sensors allowed over 3000 measurements to be obtained at TMI 2). In order to assess and learn from the TMI 2 accident, an effort was completed to evaluate sensor survivability and qualify instrumentation data and associated uncertainties (Rempe and Knudson, 2013, 2014). This effort used several techniques, including comparisons with data from other TMI 2 sensors, analytical calculations, laboratory testing, comparisons with sensors subjected to similar conditions in large-scale integral tests, and other insights available from post accident examinations. Several examples are highlighted here to illustrate important insights gained from TMI 2 sensor and data evaluations.

Although post-accident examinations provided insights about the endstate location of core materials, such insights were not available until years after the accident and they provided no indication of the timing of accident progression. However, the simultaneous increase in source range monitor count rate, RCS pressure, and cold leg temperatures (see Fig. 5) provided a much earlier indication that a major relocation of core materials occurred between 224 and 226 min after the start of the accident.

A sharp pressure spike in the containment from wide range pressure measurement (see Fig. 6) was initially dismissed as electrical noise. Calculations assuming this peak containment pressure yielded peak containment temperatures of 650 °C (1200 °F), much higher than the measured 93 °C (199 °F) peak temperature data. However, photos of damaged components (e.g., a melted phone, collapsed storage drums, etc.), supported the accuracy of this single data point indicating a hydrogen burn occurred in the TMI 2 containment. Further investigations revealed that the sampling rate for obtaining containment temperature was limited. Hence, experts confirmed the accuracy of the measured peak containment pressure.

Post-accident evaluations also attributed data unavailability to computational limits, such as storage memory, inadequate paper or ink, insufficient sampling rates, and “preset” limits associated with anticipated operating ranges. For example, the lower pressure limit prohibited data being obtained below 11 MPa-gauge (1600 psig) by the RC-3B-PT1-R RCS pressure sensor (see Fig. 7).

Analyses

Analyses initially relied on limited TMI 2 instrumentation data and available knowledge of severe accident phenomena to predict core damage. Results from chemistry evaluations of RCS water confirmed that much of the fuel cladding had failed, resulting in the release of billions of curies of fission products to the RCS and the containment. High radiation levels in the containment and in many areas of the auxiliary building initially delayed forensics investigations. RCS water streamed prohibitive radiation levels that prevented access to any location where reactor coolant resided. Early analyses, such as GEND (1981) and LANL (1983),

were essential in developing an understanding of when the core became damaged, the extent of such damage, and what hazards might be encountered during future activities after the vessel head and upper plenum structures were removed.

GEND (1981)

Results from GEND (1981), which compared results from several early evaluations, provided minimum and maximum bounds for core damage to establish a “reference” description for the core endstate. This comparison provided the basis for developing tooling and procedures for subsequent TMI 2 inspections, sample acquisitions, and defueling. Key insights from such evaluations included:

- *Fuel failure:* During the period of core uncover (from about 100 to 174 min), virtually all the rods were predicted to reach temperatures in excess of 757 °C (1394 °F), and more than 90% were expected to have failed. Estimated times when cladding failure occurred at temperatures from 757 °C to 877 °C (1394 °F–1610 °F) ranged from 137 to 142 min after the start of the accident. This coincides well with an estimated 3-min time for fission products to be transported to the containment radiation monitors, which responded at 145 min.
- *Cladding oxidation:* The exothermic cladding oxidation reaction contributed to rapid core heatup. Steam rising from lower core regions carried energy to upper core regions, increasing fuel rod temperatures. Hot zircaloy in upper core regions may have been fully oxidized, and the upper half of the core was estimated to be embrittled.
- *Liquefied fuel formation:* During the period of core uncover, essentially all the reviewed investigations predicted liquefied fuel would have been produced in small quantities. Estimates for peak fuel rod temperatures varied from 2127 °C to 2627 °C (3860 °F to 4760 °F). At temperatures above 1902 °C (3455 °F), GEND (1981) observed that experimental evidence indicated UO₂ fuel pellets in contact with the cladding can be dissolved by zircaloy, forming a liquid phase of Zr-U-O termed “liquefied fuel.”
- *Core component damage:* Analyses indicate that axial power shaping rods, control rods, burnable poison rods, spacer grids, and guide tubes would have experienced damage. Many of these materials were predicted to contribute to formation of an in-core debris bed with fused portions of relocated core rubble. Because the zircaloy cladding of the burnable poison rods oxidized over the same region as the cladding on the fuel rods, these rods were also predicted to fragment. GEND (1981) also estimated that upper plenum temperatures would melt Beryllium-Nickel material that attaches the control rod guides (brazements) to the structural support plates in the upper plenum. Stainless steel components, such as the fuel assembly upper end fittings, were also predicted to have melted or fused at their contact points within the plenum. Control rod spider failure and leadscrew distortion would also be likely.
- *Cladding fragmentation:* At 174 min, with the coolant mixture level at about 1.5 m above the bottom of the core, one RCP in the B loop was turned on for 19 min. The sudden influx of cold water to the core thermally shocked the embrittled cladding, causing fragmentation of the ZrO₂ and UO₂. These fragmented materials were predicted to either form a debris bed above the axial mid-plane of the core or increase the size of any existing debris bed. Although substantial quenching of the rods could occur, the debris bed would have remained hot and in contact with steam.
- *Major core material relocation:* The next major change in core condition occurred between 222 and 226 min into the accident. As illustrated in Fig. 5, source range monitor data showed a sharp increase in activity, the primary system pressure increased even though the block valve was open, and the cold leg temperatures of both the A and B loops increased. Estimates based upon thermocouple and Self Powered Neutron Detector (SPND) data indicate that temperatures of 530 °C (980 °F) were reached at locations 25–75 cm above the bottom of the fuel rods. GEND (1981) speculated that additional core damage occurred during this time. Given the existence of oxidized and embrittled cladding prior to about 225 min, it is possible that “unstable thermal hydraulic conditions” developed, fractured additional cladding, and led to some additional slumping of the core and densification of the debris bed. A steam blanket may have formed below the lower debris bed crust, blocking coolant ingress but permitting additional zircaloy oxidation and hydrogen formation. On the basis of available instrumentation data, no apparent change in the condition of the core occurred after about 226 min.

LANL (1983)

LANL (1983) provided an updated core damage assessment using an integrated system of computer codes, MIMAS and TRAC-PF1, to simulate heat transfer and fluid dynamic processes. This accident progression analysis, which considered observed events, initial examinations, and sample analysis results, was performed to aid development of equipment and procedures for cleanup and recovery of TMI 2 and to identify important data that should be collected in future examinations to reduce phenomenological uncertainties. The accident was analyzed from the initial loss of main feedwater to a point in time just after HPCI and subsequent core reflood occurring at 3 h and 20 min. Results indicated that the Inconel grid spacers melted first, followed by melting of the upper 80% of the control rods, and then fragmentation of the upper 80% of embrittled fuel rods. Degraded material relocated to lower core locations where a debris bed formed with a packing fraction of 30% between fuel rod stubs and 44% above these stubs. The calculated debris generation and packing fractions, in conjunction with the TMI “Quick Look” observations, indicate that 22% of the fuel rod debris would be relocated from the core region. The hydrogen production during the accident transient was estimated to be about 400 kg (880 lb_m), with the majority (about 75%) being generated during reflood. As noted below, defueling efforts in 1986 revealed that the amount of core materials predicted to relocate by LANL several years earlier was fairly accurate.

Examinations

Quick Look examinations and ultrasonic surveys

The first direct visual observations of TMI 2's core were the three "Quick Look" examinations conducted on July 21, 1982, August 5, 1982, and August 12, 1982, over 3 years after the accident. Each of these examinations was performed by inserting a small camera into the reactor vessel through one of several control rod drive lead-screw locations near the center of the reactor vessel head, thus near the center of the core. This was accomplished by removing the control rod lead screw and then lowering, by gravity, an approximately 1.5" (3.8 cm) diameter camera with lighting into the lead screw opening. Personnel introduced the camera into the lead screw opening while standing on a work platform located on top of the reactor vessel service structure.

On the first examination on July 21, 1982, "Nothing was observed until the camera encountered a rubble bed approximately 1.5 m (5 feet) below the top of the core region." (GEND, 1983 from Volume 1, Page 1–3) The discovery of this void instantly communicated the gravity of the accident. In 1983, ultrasonic scanning surveys were used to determine the shape and dimensions of materials remaining in the core cavity (US NRC, 2016). These surveys indicated that the voided cavity volume was approximately 26% of the original core region. Three years later, in 1985, when the upper plenum was removed from the reactor vessel, the extent of this damage was observed.

The most fully exposed and vulnerable component in the reactor vessel internals is the upper core support grid. It is the lowest, or "bottom," structural member of the 55-ton reactor vessel upper plenum structure. The design functions for the upper plenum and the upper grid are to index the fuel assemblies by maintaining design clearance between the upper end fittings of each of the 177 fuel assemblies, to sheath and protect the withdrawn or partially withdrawn 69 control rods, to prevent fuel assembly lift due to upward flow forces by providing hold-down force by fuel assembly spring compression, and to accomplish these functions simultaneously on all 177 fuel assemblies and all 69 control rods. The "Quick Look" examinations revealed the extent of structural melting and voiding on the upper grid (see Fig. 8). Data from Quick Look examinations were critical for designing defueling equipment tools and fixtures.

Later examinations and endstate

Images obtained prior to and during defueling, which was an essentially vertical mining process, provided evidence where damage sustained by internal support structures and penetrations was more severe (e.g., Fig. 9). Using examination information, along with results from analyses based on qualified instrumentation data, a debris endstate configuration figure (see Fig. 10) was developed that identified the location of fuel containing materials within the reactor vessel, including granular debris, crust, partially intact fuel assemblies, and "corium," a term used to describe previously molten material containing fuel, clad, and structures. As additional examination information was obtained, this figure was updated.

Examinations also provided insights about the damage induced by relocating core materials to the lower head and its penetration nozzles (see Figs. 10 and 11, Rempe et al., 2012). The most severe damage was observed in nozzles located within the "hot spot" where vessel steel examinations indicated peak temperatures occurred (e.g., the nozzle located at position H8). As discussed in Wolf et al. (1994), examinations indicated that the observed damage was not related to the embedded debris height (e.g., nozzle L6 was submerged in debris, but remained undamaged) and that lower portions of the nozzles appeared to have been protected by crusts that rapidly formed near vessel surfaces (e.g., note undamaged region at the base of nozzle H8).

As noted above, earlier investigations concluded that approximately 20% of the core materials relocated as a liquid phase and solidified in lava-like formations in the core bypass region, the core support assembly, and the reactor vessel lower head. Later evaluations (Russell and McCardell, 1989) estimated that uncertainties for relocated masses at each location ranged from 5% to 40% (regions in which defueling was completed had less uncertainty).

Fuel removal from TMI 2, which was initiated on November 12, 1985, continued for 5 years. A total of 133,000 kg (293,000 lb_m) of the 140,000 kg (310,000 lb_m) of fuel, cladding, structural and control materials was removed, including upper

Lessons learned

Numerous lessons were learned from the TMI 2 accident. Actions were taken by the global nuclear community—both by the industry and the regulators—to address these lessons. These lessons included issues discovered, or encountered, from the first seconds of the sequence of events to those that were identified much later through fine scrutiny of the event.

Examples of the first issues to be encountered were those that were highly obvious, such as the obscure and confusing valve status indication for the PORV block valve's (RC-V2's) indicator light location (behind the main control panel, on a waste system indicator panel, not readily visible to the operators), to those less obvious, such as the operator focus to prevent the pressurizer from "going solid." The first, regarding the location of indication lights for the status of the PORV block valve and other similar issues, led to changes in the layout of instrumentation panels and consideration of human factors in control room layouts not only at TMI 2 but throughout the global nuclear industry. Operator actions to throttle ECCS flow were based on prior training that emphasized avoidance of a solid pressurizer. Thorough scrutiny of these actions led to industry-wide training requirements to ensure that the operators understand basic principles of the specific plant design and operation on which they were licensed, combined with engineering measures and procedures to prevent undesirable plant conditions or status.

Careful scrutiny of the first 24 h of the accident highlighted issues regarding the preparedness of plant radiological personnel for unanticipated extreme radiological conditions, the complexity of plant owners' accountabilities for emergency preparedness along with responsibilities of ensuring that local, state and federal agencies and their responders were able to conduct their own specific accountabilities in coordination with the plant operators if a future accident should occur.

The nuclear industry implemented actions to ensure that lessons learned from TMI 2 were identified and addressed, including establishing the Institute of Nuclear Power Operations (INPO), an independent organization dedicated to operational safety in nuclear power plants. Established in 1979, INPO activities to enhance nuclear plant safety and reliability are reflected through key programs: periodic on-site evaluations of each nuclear plant and corporate support organizations, training and accreditation, events analysis and information exchange, and technical assistance (INPO, 2007).

NUREG-0600 (US NRC, 1979) documents results from the inspection effort undertaken by NRC after the TMI 2 accident. In this NUREG, which was published 5 months after the accident, the NRC Office of Inspection and Enforcement identified six areas with inadequacies:

1. Equipment performance (failures and maloperation)
2. Transient and accident analyses
3. Operator training and performance
4. Equipment and system design
5. Information flow, particularly during the early hours of the accident
6. Implementation of emergency planning.

NUREG-0660 (US NRC, 1980a) provided a comprehensive list of actions to address inadequacies for each of these areas. The Commission, however, only approved specific items from NUREG-0660 for implementation, and NUREG-0737 (US NRC, 1980a,b) provided guidance that each plant owner could utilize for implementation. This far-reaching NUREG addressed the higher priority of the lessons-learned from the TMI 2 accident. As discussed above, these lessons issues led to changes in system design, system hardware and instrumentation, operator training, control room layout to address human factors, philosophies for plant management and leadership, and emergency preparedness and planning.

NRC also identified and took actions to address their own inadequacies, including insufficient knowledge about severe accident phenomena, inadequate infrastructure to monitor an accident and to provide timely emergency response actions, insufficient attention to prior plant operating experience, and inadequate monitoring of licensee performance. For example, to address concerns about oversight, the NRC resident inspector program was expanded to provide full-time staff presence at all operating plant sites. The NRC also increased its use of probabilistic risk assessment, and in response to comments raised by the Advisory Committee on Reactor Safeguards, the agency adopted a safety goal—a quantitative objective in terms of acceptable risk to which plants could be assessed (US NRC, 1986). This latter action became increasingly important as it became apparent that some of the newly imposed requirements on licensees might actually hinder safety. Ultimately, a backfit rule was implemented to provide a basis for developing and evaluating new requirements (Ahearn, 1989).

Conclusion

TMI 2's fate was sealed in the first 120 seconds of the accident due to a combination of equipment failure (failure of the PORV to reclose), inadequate instrumentation system design (no indication to alert the operators to the unrecognized "open" PORV for the subsequent 140 minutes), and inadequate operator training. Only during the 'Quick Look' inspection, on July 21, 1982, over 3 years after the initiating events on March 28, 1979 was the extent of damage to the TMI 2 core discovered. The severe accident that followed the initiating events resulted in extensive core uncover, cladding failure, fuel melting, structural degradation, radioisotope release, and more than a decade of clean up, and defueling activities. Despite the serious damage to the reactor, studies have concluded that radiation releases during this event had negligible effects on the physical health of individuals or the environment. As discussed within this chapter, investigations following the accident led to changes that addressed multiple institutional issues

throughout the nuclear power industry. Changes were implemented in control room design, operator training, emergency preparedness, and the regulation of commercial nuclear power plants. Ultimately, the actions taken to address the TMI 2 accident enhanced the safety of the operating fleet.

Glossary

Becquerel (Bq) A unit used to measure radioactivity, which refers to the amount of ionizing radiation released when an element (such as uranium) spontaneously emits energy as a result of the radioactive decay (or disintegration) of an unstable atom. Radioactivity is also the term used to describe the rate at which radioactive material emits radiation, or how many atoms in the material decay (or disintegrate) in a given time period. As such, 1 Bq represents a rate of radioactive decay equal to 1 disintegration per second, and 37 billion (3.7×10^{10}) Bq equals 1 curie (Ci).

China Syndrome A fanciful term—not intended to be taken literally—that describes the fictional result of a nuclear meltdown scenario, whereby reactor components melt through their containment structures and into the underlying earth, “all the way to China.”

Corium A lava-like material created in the core of a nuclear reactor during a meltdown accident; also called fuel containing material (FCM) or lava-like fuel containing material (LFCM).

Curie (Ci) A unit used to measure radioactivity, which refers to the amount of ionizing radiation released when an element (such as uranium) spontaneously emits energy as a result of the radioactive decay (or disintegration) of an unstable atom. Radioactivity is also the term used to describe the rate at which radioactive material emits radiation, or how many atoms in the material decay (or disintegrate) in a given time period. As such, 1 Ci is equal to 37 billion (3.7×10^{10}) disintegrations per second, so 1 Ci also equals 37 billion (3.7×10^{10}) Becquerels (Bq).

Design Basis Accident One category of the postulated accidents used to set criteria and limits for the design and sizing of safety-related systems, structures, and components.

Exclusion Zone The approximately 30-km radius ($\approx 2,600 \text{ km}^2$) area surrounding ChNPP managed (since April 2011) by the State Agency of Ukraine on Exclusion Zone Management (SAUEZM). This Agency is administratively within the State Emergency Service of Ukraine, itself managed by the Ukrainian Ministry of Internal Affairs.

Group of Seven (G7) International intergovernmental economic organization consisting of seven major developed countries: Canada, France, Germany, Italy, Japan, the United Kingdom and the United States, which are the largest International Monetary Fund advanced economies in the world.

International Nuclear and Radiological Event Scale (INES) A tool for communicating the safety significance of nuclear and radiological events to the public. Events are rated at seven levels: Events without safety significance are rated as Below Scale/Level 0. The scale is logarithmic—that is, the severity of an event is about 10 times greater for each increase in level of the scale.

Operating Reactivity Margin (ORM) The extra reactivity that would arise if all control and safety rods were withdrawn; expressed as the number of “equivalent” or “effective” control rods of nominal reactivity worth remaining in the reactor core. This number is a calculated value; it is not equivalent to the number of actual control rods in the reactor core but depends on several variables, such as the power density distribution (the degree of neutron flux where the control rods are positioned which affects how many neutrons the control rods absorb).

Reactivity A measure expressing the departure of a reactor system from criticality. A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

Roentgen (R) A unit of exposure to ionizing radiation. It is the amount of gamma or x-rays required to produce ions resulting in a charge of 0.000258 coulombs/kg of air under standard conditions.

Introduction

At approximately 00:23:40 (Kyiv-time) on April 26, 1986, a safety test led to the most severe accident in the history of commercial nuclear power occurred at Unit 4 of the Vladimir I. Lenin Nuclear Power Station at Chernobyl [Ukr: Chornobyl] (the Chernobyl Nuclear Power Plant or ChNPP). After a brief overview of the ChNPP4 design, this chapter summarizes key events of the accident evolution and Accident Management Actions (AMAs) taken during the initial days and months, including (see Fig. 1) an initial domestic effort to confine radiation releases in a “sarcophagus” (formal name “Object Shelter” or OS) followed by an international effort to provide a more robust building, known as the New Safe Confinement (NSC). Root causes of this event are discussed. In addition, this chapter summarizes measures taken to enhance the safety of nuclear power plants—in particular, RBMKs.

RBMK design and Chernobyl plant overview

The development of nuclear power as a large-scale provider of electrical energy received significant support from the Soviet government. The advent of what would become the “high power reactor – channeled” or RBMK (РБМК: Реактор Большой Мощности – Канальный) was heralded on June 27, 1954 by the startup of the 5 MWe (30 MWt) Obninsk experimental prototype; a graphite-moderated, light-water cooled reactor. The Obninsk reactor was the first of a series of test reactors built during the 1950s and 1960s, leading to the first commercial large-scale RBMK-1000 at Sosnovy Bor (the Leningrad NPP) achieving full-power operation in January 1974.

RBMK design

The RBMK is a heterogeneous, thermal neutron, graphite-moderated, channel-type, boiling-water nuclear reactor with on-line refueling. As originally designed, the light-water coolant flowed upward through 1661 zirconium – 2.5 niobium alloy (Zr-2.5 Nb) pressure tubes (fuel channels) containing slightly-enriched (1.8%–2.0%) UO_2 fuel assemblies within square graphite stacks of blocks (250 mm $\times$ 250 mm of various lengths) acting as the moderator. As shown in Fig. 2, each fuel channel contains two 3.5 m long fuel assemblies stacked one on top of the other providing an “active” fuel length of approximately 7 m. Each assembly consists of 18 Zr-1Nb clad fuel rods distributed in two concentric rings of 6 and 12 rods about a central hollow Zr-1Nb support rod and held in place by stainless steel spacer grids along the assembly length.

The core (see Fig. 3) is arranged in the form of a large vertically-oriented cylinder (equivalent diameter of 11.8 m and height of 7.0 m). The axially central fuel portion is surrounded by an annular graphite reflector (columnar stacks of blocks with equivalent thickness of 0.88 m), and the core is covered on the top and bottom with an additional 0.5-m graphite reflector—making the effective overall dimensions of the graphite stack approximately 13.8 m in diameter and 8.0 m in height. Radial core support is provided by 156 water-cooled support tubes situated at the outer periphery.

The graphite structure included a total of 2488 channels for fuel rods, control rods, and instruments (at the core periphery). In the case of the fuel channels, between the outer wall of the pressure tube and the inner wall of the hollowed-out graphite block are graphite spacer rings of two different diameters fitted alternately to the tube and graphite channel. These provided a path for heat flow from the graphite stack to the pressure tube, while additionally permitting pressure tube expansion. Nominal average operating temperature for the graphite was 600 °C, while the maximum permitted temperature was 750 °C. A mixture of nitrogen and helium gas was circulated within the core between blocks in the graphite stack to prevent oxidation and increase heat transfer to the coolant.

The in-core control system channels were similar to the Zr-2.5Nb clad fuel channels. During operation, control was accomplished using 211 rods with detectors arranged into five functional groups: manual regulation rods (RR), emergency power reduction or SCRAM rods (AZs), overall automatic power regulation rods (OAR), local automatic regulation (LAR), and axial power

Fig. 2 Cross-sectional views of RBMK Fuel Channel and Assembly (Sich, 1994a).

Fig. 3 Cross-sectional views of the ChNPP4 Reactor Vault (Sich, 1994a).

regulation rods (APRs) with shortened absorbers. Except for the rods used for automatic power regulation (e.g., the OARs and LARs), top-inserted control rods (the RRs and AZs) had “followers” or “displacers” connected below the neutron absorber section (for the bottom-inserted APRs, the follower had a displacer as a leader that was located above the neutron absorber section). As a top-inserted control rod is raised out of the core, the follower replaces it—helping to smooth out the local neutron flux. When fully withdrawn, the end of the follower was located 1 m above the bottom of the fuel portion of the core. Hence, in the lowest one meter of the core, control rod followers were too short: they did not extend to the bottom of the core. Those channels were filled with water that acted as a neutron poison relative to the graphite. Hence, if fully withdrawn control rods were reinserted, positive reactivity was also initially inserted into the lowest regions of the core, decreasing the margin to boiling-induced voiding.

As shown in Fig. 4, coolant was circulated through two primary loops with a 14.7% steam two-phase mixture fed from the fuel channels to four steam-separator drums—located in pairs above and on each side of the reactor—then, coolant flowed directly to two 500 MWe turbines (TG7 and TG8 for ChNPP4). The separated water, together with fresh feed water, was returned to the bottom of the core through downcomers by six 4 MWe main recirculation pumps (MCPs). Each MCP increased the coolant pressure by about 2 MPa to an operating pressure of approximately 9 MPa.

Fig. 4 Cross-sectional view of the RBMK-1000 main building (Sich, 1994b).

Advantages

The RBMK, considered the Soviet Union's "national reactor" (Medvedev, 1991), has several important and rather significant advantages compared to Light Water Reactors (LWRs). Operational advantages of the RBMK include the following:

- Uranium-graphite reactor systems cooled by boiling light water are the most accessible for a country with a moderate economic base and technological infrastructure. Although the RBMK has a more complex structure than a typical pressure vessel-based reactor, similar designs were not without precedent in fossil fuel plants and the absence of complex and expensive steam generators proved to be a distinct advantage.
- Besides not requiring an outer structure surrounding the reactor core (such as a pressure vessel for LWRs or pre-stressed concrete vessels for gas reactors), the graphite channel reactor offers flexibility in reactor design. Because of the lack of restriction on core size, the use of standard structural elements was possible for RBMKs. Its modular construction allowed major reactor components to be fabricated at existing manufacturing plants with relatively simple transport and assembly at the plant site.
- RBMKs use lower enrichment uranium and could be used for the production of U-233 from Th-232.
- The RBMK can be refuelled online without interrupting reactor operations, resulting in a higher capacity factor.
- The RBMK permits superheating of steam and channel-by-channel control of flow rates (implying higher thermodynamic efficiency and reliability). Each channel's integrity and operational parameters could be monitored separately; damaged channels could be replaced under operation.
- The use of small-diameter pressure tubes precluded the large break loss of coolant accidents possible with western-designed LWRs.

Disadvantages

Some RBMK features, which were intended to make it more efficient, actually introduced significant disadvantages. Features identified as design faults include the following:

- The over-moderated core was designed to enhance neutron economy required for low fuel enrichment operation. Because graphite is utilized as a moderator, the water coolant effectively behaves as a slight to moderate neutron poison. Operational experience led to a recognition that if the water voids through boiling ("positive void coefficient" manifested mainly at low-power in "mature" cores with high burnups) or if coolant in control rod channels is displaced by graphite followers (a major design flaw), positive reactivity is introduced (Dyatlov, 1996).
- Although the RBMK can be considered a "modular" system scalable to larger core sizes, this also results in a neutronic loosely-coupled core that is difficult to control—particularly at low power levels when the positive void coefficient was more prevalent. There is a high sensitivity of the neutron field to reactivity disturbances, necessitating a complex, computer-based, control system for stabilizing the distribution of energy generation in the core. Moreover, the large core size gives rise to a potential for local critical masses to form within the core (USNRC, 1987; Sich, 1994a,b).
- The graphite followers attached to the bottom of the control rods were designed to improve neutron economy while in the core and to maximize reactivity change upon control rod insertion. However, the followers and control rods fit closely in the channels—hence their motion was damped significantly by the surrounding water, resulting in a very long insertion time (~20 s) compared to typical insertion times of 2 s [for Pressurized Water Reactors (PWRs)] and 4 s [for Boiling Water Reactors (BWRs)]. In addition, the length of the followers was too short: this left a water gap at the bottom of the core, causing a "positive scram" effect that supplemented activity insertion due to voiding water.
- Besides the complexity of the inlet-outlet piping as the heat-transfer agent of each channel and the large amount of thermal energy accumulated in the metal structures, fuel elements, and graphite stack, RBMKs have a limited capability to accommodate structural effects of temperature transients (stresses and strains)—namely in the zirconium-to-stainless steel transition welds at the inlet and outlet to the fuel channels in the core (US DOE, 1989).
- No emergency or warning signals were provided to generate alarms when key parameters for the reactor reach points requiring emergency protection system actuation. This was a "clear violation" of Article 3.1.8 of NSR-04-74 (Atomizdat (1976); INSAG, 1993; Mosey and Varley, 2006).
- The design basis accident (DBA) for an RBMK-1000 was the near-simultaneous rupture of a maximum of two-to-four fuel channels (of 1661 total). In such a case, the Emergency Core Cooling System (ECCS) and the Accident Localization System (ALS—the emergency pressure suppression system comprised of steam distribution headers and corridors as well as the two-level steam-water bubbler pool) underneath the reactor were designed to withstand the associated over-pressurization of the thin stainless-steel "skin" (so-called Component KZh) that surrounds the core. If more channels fail, it was postulated that the 2500 t-equivalent Upper Biological Shield (UBS) (see Fig. 3) would be lifted upwards—shearing more of the channels and eventually leading to catastrophic failure of the entire system. The Zr-Nb2.5%-to-stainless steel transition welds (diffusion bonding process) at the top and bottom of each of the 1661 fuel channels were considered to be the weakest points in the main coolant circuit and the most likely to fail according to safety analyses (USNRC, 1987).
- Fuel channel and graphite block integrity was also a concern. Due to long-term irradiation over the course of operations, the size and physical properties of these graphite moderator blocks change, and the Zr-2.5Nb pressure tubes suffer from creep, oxidation and hydrogen absorption. Stress corrosion cracking had been observed in the transition welds.

- The lack of an RBMK pressure vessel, while less expensive in terms of construction and maintenance associated with creep, neutron embrittlement, and pressurized thermal shock encountered by other LWRs, is a safety deficiency. In the context of defense-in-depth, the pressure vessel represents a major line of defense against a release of radiation in case of an LWR accident. The RBMK graphite stack (including the core) is located in a sealed cylindrical container formed by a 14.52 m diameter and 9.75 m high steel shell (“Component KZh” or “skin” in Fig. 3) 16 mm thick with close to 4000 penetrations, including primary coolant piping. This container serves as a gas barrier as well as primary structural restraint and support for the graphite stack. It is this shell that, if compromised, will release steam that could raise the UBS and shear coolant channels (IAEA, 1993a,b).
- RBMK reactors have no “containment” structure: there is no “final” robust engineering safety barrier between the reactor and environment. At the time of the accident, RBMKs incorporated a “confinement” pressure-barrier system based on the (then) DBA basis noted above: the rupture of a maximum of two-to-four channels to mitigate against the breach of Component KZh. The ChNPP4 reactor hall (the region above the UBS, with dimensions approximately 24 m wide × 80 m long × 35 m high)—similar to those at other RBMK units—was constructed of reinforced 1.5 m-thick concrete walls for the lower bay and a steel frame roof with precast concrete panel sheathing for the walls of the high bay. This reactor building was only designed to withstand normal building structural loads (USNRC, 1987).

ChNPP

ChNPP4 is located in the eastern part of a large, sparsely forested region called the Belarusian-Ukrainian *Polissia* (woodland) along the banks of the Pryp'yat' (Pripiat) River. Just prior to 1970, Soviet central planners decided this remote region of rural Ukraine, would be suitable for the location of Ukraine's first nuclear power plant. At the start of the plant construction in 1970, the population density was approximately 24 inhabitants per square km, and the population of the entire Chernobyl region was only about 47,000. At the beginning of 1986, the population within the later-defined 30-km Exclusion Zone surrounding the plant was close to 100,000 people, of which 49,000 lived in the newly-built “atomic” city of Prip'yat—located 3 km to the northwest of the plant industrial site.

The first set of reactors at ChNPP, Units 1 and 2, were the third pair of “first generation” RBMK-1000s, (completed in 1972 and 1978); Units 3 and 4 were second-generation reactors (completed in 1977 and 1983); and Units 5 and 6, which were under construction at the time of the accident (85% and 15% completed), were third generation reactors and located approximately 1.5 km southeast of Units 1 through 4. A reservoir, 21.4 km² in area and 5 m deep, along the Prypiat River was built to serve the cooling needs of the first four units, while two cooling towers were built on the site of Units 5 and 6 to serve their needs.

Rated at 3200 MWt (1000 MWe), Unit-4 was “physically started” on November 11, 1983, achieved criticality on November 25, 1983, was connected to the grid on December 21, 1983, and began commercial operation on March 25, 1984. By April 25, 1986 (1 day prior to the accident), ChNPP4 had reached the end of its first operating cycle with a core-average burnup of 10.9 MW · d/kgU for its initial 190.3-t UO₂ fuel load (Borovoi and Sich, 1995). Following a relatively routine reactor safety experiment, a maintenance outage was scheduled for the following day.

The accident

At approximately 00:23:40 (Kyiv-time) on April 26, 1986, after 865 calendar days and 715 effective full-power days in operation, the most severe accident in the history of commercial nuclear power occurred at Unit-4—characterized as a Level 7 Major Accident per the International Nuclear Event Scale (IAEA, 2008). The accident significantly damaged Unit 4 (see Fig. 5). It led to several explosions in which significant quantities of reactor materials (in the form of large chunks of graphite, pressure tubes, and fuel assemblies) were hurled up to 150 m radially from the core onto the buildings and grounds of the plant industrial site. These materials started more than 30 fires on the roofs of the Unit 3 and 4 Auxiliary Building, the deaerator roof of Unit-3 and the “machine hall” above turbine generator TG7. Much of the roofing of these buildings was pitched with tar (bitumen) that exacerbated the fires. Within ChNPP4, other fires started due to the presence of large quantities of lubricating oil pipes and containers damaged as a result of the explosions. The immediate task was to address the fires. By 02:15, fires on the roof of the Machine Hall were contained, by 02:35 fires on the reactor and auxiliary buildings were put out, and by 06:35 all fires in the vicinity had been extinguished (Medvedev, 1991).

Sequence of events

Precise details regarding some of the events that occurred during this accident may never be known. Sich (1994a) reviews available references to develop a detailed chronology: significant events during the first few hours of the accident include the following:

- At 01:06 on 25 April, operators started reducing power in preparation for the TG8 coastdown test.
- At 03:47, reactor thermal power is 1600 MWt.
- At 07:10 on 25 April, the ORM was 13.2 control rods equivalent (in violation of the ORM limit of 15 equivalent rods that requires reactor shutdown (INSAG, 1993a,b)]—likely due to operators compensating for xenon buildup from the descent to half

Fig. 5 A mid-August 1986 view of the remains of the Chernobyl NPP Unit-4 from the south-southeast at an elevation of 250 m. Alexander Sich, personal collection, unsourced photograph courtesy of Valentin Ivanovich Obodzinskiy of the Kurchatov Institute.

power). More violations (procedural overrides and control rod manipulations) continued throughout the day. These violations occurred because the Kyiv load dispatcher imposed an additional nine-hour delay for starting the test when the reactor was at slightly less than half power (1600 MWt).

- At 14:00, the ECCS was disconnected as part of the test (to avoid possible actuation that would require repeating the test).
- At 23:10, the load dispatcher permitted continuation of power reduction. Because of the imposed delay in power reduction, a new shift—which was not briefed on details of the safety test—took over operations.
- At 00:25 on 26 April, the power dropped to 650 MWt in direct violation of normal safety test procedures. The test was designed for a power level of 700 MWt, so the reactor should have been shutdown immediately. This is considered the official “start” of the accident.
- At 00:28, the local automatic control rod positioning system, which monitors and maintains local power in 12 core zones, is switched off; but the operating staff also makes an error by switching to fully automatic control without entering the hold power at the level required for the safety test. As a result, the reactor power drops to below 30 MWt and xenon poisoning “forces” operators, at multiple times, to lower the ORM (drastically attempting to “save” the experiment). No fewer than six times were trip interlocks overridden (including ORMs) to permit the experiment to continue.
- By 01:03, the power level was stabilized at approximately 200 MWt—well below the 700 MWt required for the test. Note, however, the risk of running the experiment at low power was not de-scribed in the operating instructions, so operators proceeded with the test.
- From 01:07 to 01:23 the ORM hovered between five and eight equivalent rods in a difficult attempt to compensate for xenon buildup in a neutronically-decoupled core by (a) balancing feedwater flow rate (the coolant was barely below saturation temperature and pressure—just below voiding—and actually exceeded, by four times, the balanced flow rate), (b) exceeding vibrations limits due to cavitation concerns, (c) hovering steam drum separator levels near the emergency level (operators blocked the emergency trip signals related to low steam pressure followed by manual replenishment of water in the steam drums), and (d) operators removing some of the manual control rods entirely. In short, the core was quasi-stabilized in such a state that any insertion of positive reactivity would lead to a loss of control of the reactor.
- At 01:23:04, the TG8 safety experiment started with the command “Oscillograph on!” The TG8 stop valve was closed leading to an increase in pressure (hence a decrease in reactivity). At the same time, the flow rate began to fall due to MCPs being powered by spinning-down TG8. As a result, voiding (steam) increased—inserting reactivity.
- At 01:23:40 the AZ-5 scram signal was initiated because power was rapidly increasing (at that point, already 320 MWt) and strong and frequent shocks are felt. As control rods slowly descend into the core, the flawed follower design inserted reactivity at the bottom of the core. By 01:23:45, the calculated power peak reaches approximately 470 times nominal full power or 1500 GWt. By 01:23:48–49 the core was destroyed.

Accident management actions

In response to this accident, which had not been previously hypothesized, actions were taken during the initial days and months. To this date, activities continue to monitor conditions at the site.

Actions during the active phase

The “Active Phase” of the Chernobyl accident (see Fig. 6) is defined as the time period between the following:

- the initial destruction of the core, caused by the violent interactions of fragmented fuel as it came into direct contact with the primary coolant resulting in a massive steam explosion, to
- a sharp drop (factor of $\sim 10^3$ – 10^4) in radionuclide releases to the environment about 9.5 days later.

During the morning of 26 April 1986, a Government Commission was formed and charged with coordinating accident “liquidation” (mitigation) tasks, along with the mobilization of resources necessary to carry out such tasks (Medvedev, 1991). Initially, Serhiy Vasylovych Shirokov (Head of the Division of Nuclear Power Stations in the Ukrainian Ministry of Energy and Electrification), who was assigned coordinator of mitigation efforts in Kyiv, indicated that it was very unclear what had happened—mainly because Anatoliy Diatlov (Deputy Chief Engineer of Units 3 and 4) and Viktor Briukhanov (Plant Director) refused to believe what had occurred. Although some plant personnel risked their lives to climb to near the roof to observe the core, they were either afraid to describe what they witnessed or were not believed (Read, 1993). The first official recognition of what occurred was around 15:00 on April 26 (Haynes and Bojcun, 1988). An attempt to cool the reactor with water seemed to fail, although some station engineers still believed the core was being at least partly cooled by water during most of the first day. It was not until 22:00 on April 26 (more than 20 h after the explosions), when a specialist from NIKIET (the RBMK design institute) flew over the plant and confirmed Unit 4 was destroyed. It is likely that the extent of the damage was not fully recognized or understood by members of the Governmental Commission until sometime in the evening following the NIKIET specialist report.

During the Active Phase, the Soviets attempted a number of rapid-response AMAs to minimize radionuclide releases to the environment—primarily focused upon (a) the burning core and its potential impacts on surrounding structures, and (b) heavily-contaminated land in the immediate area of the plant. INSAG-1 (1986) noted these mitigation efforts:

... were, generally, quite successful... [the] dumping [of] materials into the reactor well..., supplying nitrogen to bring down the temperature in the core space and to reduce the oxygen concentration, and the construction of a flat heat exchanger beneath the foundations of the reactor building, stabilized the situation at an early stage (about nine days after the initiating power surge) of the accident.

Indeed, the reality of the situation was markedly different from the Soviet account presented in Vienna to the IAEA in August 1986. The AMAs included the following efforts (see Fig. 6):

- Approximately 1250 helicopter sorties to “bomb” or smother the burning core with 5020 t of materials. Sorties continued through the end of May 1986 primarily aimed at suppressing dust from highly contaminated areas: over 1800 total sorties were flown involving approximately 600 pilots and crews dumping 16,640 t of the following materials:
 - i. boron carbide—to prevent recriticality;
 - ii. dolomite—to generate CO_2 for a smothering gas blanket and heat dissipation;

Fig. 6 Summary of AMAs during the active phase of the ChNPP4 accident (Sich, 1994b).

- iii. sand and clay—to quench the fire and provide a filtration layer to inhibit radioisotope releases;
- iv. lead—to absorb heat, eventually cooling to help seal the core (note that vaporized lead would have led to another ecological disaster).
- Nitrogen purge gas into the reactor through coolant channels in an attempt to cool the core and limit oxidation;
- Water release from the ALS pressure-suppression pool to mitigate steam formation from potential core-water interactions;
- Construction of a sub-foundation flat-bed heat exchanger below ChNPP4 to mitigate potential core contact with the soil and ground water;
- A large 8.4-km long 30-m deep below-grade vertical concrete shield around the entire plant (dubbed “Casa Grande”) to limit contamination of ground water flowing into the Prypiat River from surface contamination and to limit any potential “China Syndrome” effects;
- Cutting down and plowing under massive amounts of contaminated woodlands (mostly conifers) located immediately to the southwest of the plant.

At the August 1986 IAEA Meeting of Experts, the official Soviet account stressed the AMAs successfully contained the burning core and eventually stopped radioactive releases into the environment:

...the reactor shaft was covered by a layer of loose mass which intensely absorbed aerosol particles... [and that] the problem of reducing fuel heat-up was solved. To reduce temperature and oxygen concentration, nitrogen from a compressor station was sent into the space under the reactor shaft... The lower slab of the reactor shaft [LBS] had been preserved and fuel was localized mainly (roughly 96%) in the reactor shaft and in compartments of the steam water and lower steam service lines.

Subsequent investigations (Sich, 1994b) revealed intervention measures were either ineffective or not implemented as portrayed by the Soviets:

- Very little, if any, of the 5020 t of materials dropped from helicopters made it into the reactor shaft, confirmed by radiochemical analyses of “frozen” corium or fuel containing material (FCM) in the lower regions of the reactor building (see Fig. 7). Therefore, the core was exposed to ambient conditions—readily releasing radioactive contaminants to the environment (Begichev et al., 1990).
- The gaseous nitrogen purge of the core was initiated after the Active Phase: the first tankers of N_2 arrived at the plant about 01:00 on May 6, 1986, coinciding with the start of nitrogen pumping. This was almost exactly 10 days following the accident (after the end of the Active Phase). The effort was soon abandoned as “a waste of time.”
- The Soviets were concerned the initial 5000 t of material dropped from helicopters could compromise the integrity of structures immediately below the core—possibly forcing the core itself into the 3200 m³ (nominal water volume) ALS pressure-suppression pool as an “assisted China Syndrome.” Core-water interactions would generate tremendous amounts of steam—increasing contamination releases to the environment. The lower regions of the reactor building were known to be flooded with water from

Fig. 7 View above destroyed Unit-4 from the northeast showing the UBS and a gaping hole downward to the reactor shaft. Also visible are piles of materials thrown from helicopters attempting to smother the “red glow.” Adapted from Alexander Sich, personal collection, unsourced photograph courtesy of Valentin Ivanovich Obodzinskiy of the Kurchatov Institute.

Fig. 8 Sectional View of ChNPP-4 showing possible corium flow paths (red). Virtually no fuel or graphite is found in the reactor shaft region. Approximately one-quarter pie-shaped section of the LBS is missing (Borvoi and Sich, 1995).

the primary system and from water pumped into core in response to the accident. The release of the water (estimated to be $20,000 \text{ m}^3$) was completed on 8 May, or 23 days after the end of the Active Phase. Releasing the water did little to nothing to mitigate releases.

- An over one-quarter pie-shaped section of the two-meter-thick, 17 m diameter, 1200 t LBS (see Fig. 8) was completely eaten away by a molten admixture of a major portion of the fuel ($135 \pm 27 \text{ t}$ or roughly 71% of the initial fuel load), the LBS, and surrounding structures flowed into the lower regions of the reactor building ALS. Only a small portion of the solidifying corium contacted the remaining water to form mounds of corium pumice.
- The corium admixture did relatively little damage to components of the ALS bubbler pool. By the end of the Active Phase, the corium admixture had broken through the LBS—this increased the potential for it to solidify (which decreased future radiation releases) because of several factors: (a) the flow extended to over 41 m from the remains of the LBS—greatly increasing surface area for cooling, (b) decay heat had fallen roughly 10–15 times since the accident (to about 50 kWt/tU), (c) freezing point depression (mixture and chemical complexification) resulted from the uptake of various materials (in particular stainless steel and serpentine) by the admixture.
- The first design version of a sub-foundation flat-bed heat exchanger, whose construction rationale was to avoid a “China Syndrome,” foresaw pumping liquid nitrogen into an excavated cavern roughly $30 \text{ m} \times 30 \text{ m} \times 2.5 \text{ m}$ in contact with the foundation. The design was later altered to employ water as the working fluid. Construction was completed on June 28, 1986 or almost 8 weeks after the end of the Active Phase. Subsequent evaluations found that the heat exchanger played no role in mitigating the accident consequences, but it did expose many workers to very high levels of radiation. The project was abandoned, and the area sealed.

- Only 6.1 km of Case Grande's proposed 8.4 km design was built. Severe surface contamination in the area of the "Red Forest," through which the underground wall was foreseen to be constructed, delayed construction... and the work was eventually abandoned. Unfortunately, the shape of the completed portion of the wall and its location between the plant and the Prypiat River effectively made it function like an underground dam for ground water naturally flowing toward the river. As a result, ground water levels rose significantly—eventually reaching the foundation of the turbine generator building.

In conclusion, little to no direct human interventions aided "natural" processes during the Active Phase: the accident stopped itself.

The sarcophagus

The "Sarcophagus" (formally called the "Object Shelter") (Fig. 1(b)) was commissioned on November 30, 1986—6 months following the accident. It was described by the Soviets as a "concrete cube" because, it was claimed, between 300,000 and 410,000 m³ of concrete was used for its construction. However, taking the cube root of these numbers yields the equivalent lengths of sides of a solid cube of concrete to be between 67 and 74 m. This is larger than the actual sarcophagus, which, in fact, is mostly empty space (Borovoi and Sich, 1995). According to structural drawings, the amount of concrete used was about 161,000 m³. Even so, much of this concrete leaked through holes in the reactor building onto the grounds of the station or was used to cover the ground to shield workers (Sich, 1996a,b). As noted in Sich (2011), "... the sarcophagus's structural integrity is questionable. Better characterized as a 'steel tent' hastily erected upon ruins rather than a 'concrete encasement,' the sarcophagus was never meant to be hermetically sealed."

The sheer size of the structure (roughly 85 m long × 140 m wide × 75 m high, constructed upon the ruins of the destroyed reactor building) and the extremely hazardous working conditions (necessitating the use of unique remote-construction methods in high radiation fields) plus a short time span of 6 months make it a unique accident clean-up and isolation achievement. After considering 18 different project proposals, a design was chosen to take advantage of the reactor building's foundation and remaining superstructure—significantly reducing costs and construction time. There were also significant disadvantages:

- structural integrity of the remaining portions of the reactor building was unknown;
- remote methods for pouring concrete did not always permit observation and review of the work;
- high radiation fields made welding key structural components impossible.

As a result, two essential deficiencies were understood to potentially threaten longer-term stability of the Sarcophagus: the unknown strengths of massive buttresses that formed the upper portions of the structure and the openings and breaks in the walls and roof (estimated to have an area of 1200 m²). In 1987–88, projects to strengthen damaged internal support structures were undertaken to prevent a potential collapse that could further weaken the Sarcophagus. Structural monitoring throughout the 1990s registered no noticeable long-term movements of internal support members, even though the area experienced an earthquake measuring 4.0 on the Richter scale in May 1990. In 1998, the US Department of Energy, in collaboration with plant personnel, successfully completed strengthening the 75 m-tall ventilation stack above Units 3 and 4, which was deemed to be "in [an] emergency condition" (Gore et al., 1998). This was an important short-term stabilization project (that supported the Shelter Implementation Plan) to prevent collapse of the stack onto the Sarcophagus prior to the start of construction of the New Safe Confinement plus Object Shelter (NSC + SO) in 2010. On February 12, 2013, a 600 m² portion of the roof of the turbine-generator building failed near the Sarcophagus due to a truss weakness—resulting in a portion of roof panels installed in 1988 to collapse. Relatively little radioactivity was released, but it necessitated short term evacuation of area workers (IAEA, 2013).

As managed by the Shelter Implementation Plan for the Safety Account of the European Bank for Reconstruction and Development (EBRD), the NSC + SO (162 m long × 257 m wide × 108 m high, 36,000 t mass, lattice construction of tubular steel members supported by two longitudinal concrete beams) (see Fig. 1C) was completed in 2018 to confine the contaminated remains of ChPP4 for the next 100 years—allowing for at least a partial demolition of the original sarcophagus, including localization, characterization, and managed removal of the core of the destroyed reactor.

Post-accident surveys, analyses, international reaction

Disposition of the nuclear fuel within the sarcophagus

Apart from the melt-through of a section of the LBS, the lower regions of the reactor building which form the ALS suffered little if any damage from their interactions with the roughly 135 t (about 71%) of the melted core's initial fuel load (see Figs. 8 and 9). Striking photographs of corium stalactites and "frozen waterfall" (see Fig. 10) as well as results of radiochemical analyses, support the notion that a "China Syndrome" scenario is virtually impossible. The corium lost much of its ability to interact with surrounding structures and quickly solidified—greatly diminishing releases and marking the end of the Active Phase due to the following (Sich, 1996a,b; Borovoi and Sich, 1995):

- Decay heat dropped to about 50 kW/t U after 9 days, and the dilution of the corium by the uptake of surrounding materials further lowered its specific heat generation.
- The chemistry of the corium admixture was strongly affected by the continued uptake of surrounding materials—especially contributions from the LBS's stainless steel and serpentine (a hydrous magnesium silicate)—which likely drove the corium's solidus temperature higher while it formed various stratified layers.

Nuclear Safety* 35(1); personal collection of Alexander Sich, unsourced photograph courtesy of Aleksandr Borovoi of the Kurchatov Institute.

- Rapid spreading over a distance up to 40 m from the epicenter just below the reactor shaft occurred immediately after the corium melted through the LBS—facilitating surface cooling and further suppressing heat generation effects.
- The formation of solidified, ceramic-like corium as well as formation of a pumice-like material when the corium contacted water. This indicates a relatively rapid cooling process ensued once the corium penetrated the LBS and flowed into the lower regions of the reactor building.

- There is little indication of blast damage below the nominal level of the LBS. Moreover, channel coolant piping which enters the core from below the LBS seems to have been pulled smoothly downward around its periphery. Rather than an explosive downward-driven motion, this appears to indicate a slow creep-induced collapse of the cruciform reactor support structure occurred due to heat generated from the approximately 75 t of solidified corium that settled around this support once a portion of the LBS melted through.
- The reactor shaft contains concrete slabs identified as sections of wall from above the Central Hall floor near the steam drum separators. The approximately 2000 tonne UBS currently rests on one of these slabs at 15 degrees from vertical with its center at 5 m above nominal (see Fig. 8). This suggests the UBS must have been hurled at least several meters into the air by the violent release of steam before landing in the mouth of the reactor shaft—pinning the wall slab beneath itself.
- The infamous “red glow” spotted and subsequently bombed by helicopter crews was actually located on the floor of the Central Hall about 15 m from the reactor shaft. This glow was not, as previously believed, located within the reactor shaft. To this day, investigations have not been able to confirm whether this is fuel-graphite rubble ejected from the core.
- Results of radiochemical analyses of close to 200 samples of corium indicate the retention of Cs-137 is higher than expected given the highly oxidizing conditions—about 35% of the initial inventory at the time of the accident.
- It is estimated (see Table 1) approximately 95% of the original 190.3 t UO₂ fuel charge at the time of the accident remains within the Sarcophagus: roughly 75% below the reactor in various forms of corium, while the balance is scattered throughout the upper portions of the structure as pulverized parts of the core and dust, including under the “Pioneer Wall” erected on the north side of the original reactor building. (Borovoi and Sich, 1995). The corium manifests in various forms—roughly characterized as black or brown pumice-like and slag-like ceramic materials as well as metallic admixtures of fuel and surrounding structural material.

Table 1 ChNPP4 fuel distribution and mass balance.

<i>Location and description</i>	<i>Fuel mass subtotal, tonne</i>	<i>Fuel mass total, tonne</i>
Upper levels of the reactor building (level ≥ 35.5 m)		37.7 ± 5 +?
• Central hall (estimate of core fragments)	15	
• Central hall (hot particles and dust)	5 ± 2	
• Central hall (under pile of materials thrown from helicopters)	?	
• Core fragments attached to UBS	5 ± 3	
• Steam separator drum areas	2 ± 1	
• Other areas above reactor	5	
• Fragments within the cascade wall of the sarcophagus	1.9	
• Turbogenerator hall (estimate of core fragments)	1.9	
• Fuel fragments beyond reactor building but under concrete	1.9	
4th floor—subreactor region (level 9.0 m)		95.7 ± 26
• Core fragments scattered upon the LBS	0.5 ± 0.2

Reconstruction of events during the active phase

The August 1986 Soviet Report to the IAEA (USSR, 1986) concluded that AMAs to smother the core with materials dumped from helicopters were effective. Four primary elements support an accident progression hypothesis quite different from that presented by the Soviets to the IAEA in August 1986:

- Reassessment of effectiveness of AMAs—indicates that AMAs were ineffective: none played significant roles in the Active Phase;
- Radiochemical analyses of FCMs—indicate no material other than proximate structures were taken up in the corium; little to no carbon compounds have been observed in the FCM—in particular, uranium carbide—seemingly precluding carburization as an activity transport mechanism;
- Radiochemical analyses of releases—release patterns vary significantly between volatiles, refractory metals, and refractory oxides; higher than expected amounts of entrained Cs-137 in corium indicate filtration-limited releases and varying transport mechanisms/paths;
- Photographic images and thermal surveys indicate that some fraction of the corium remains in the sub-reactor region and upper regions of Sarcophagus with little damage to surrounding structures by corium. There is no blast damage evident below the reactor shaft.

First proposed by Sich (1995), a peer-reviewed and un-challenged accident progression scenario, which considers the above evidence, is outlined in Fig. 11.

Immediate damage, contamination, evaluations, and health effects

The reactor core was destroyed. Approximately 135 ± 30 t of fuel (~ 70 –85% of the initial load) eventually melted and flowed downward into the reactor building's lower regions and pressure suppression pool—the latter which had been almost completely drained of water by the time of its breach. About 3.5% of the fuel (~ 6.7 t) was blown upwards out of the reactor core “shaft” and released into the atmosphere where aerosol-sized particles were eventually carried over the northern hemisphere. An estimated 25–30 t of fuel, in the form of “dust” or large, broken pressure tubes imbedded in graphite, were scattered through the upper levels of the destroyed reactor building and up to 150 m from the reactor building—the latter subsequently either “scraped” toward the reactor building and interred in the “sarcophagus” (either pushed or carried into the building by hand under extreme radiological conditions) or covered by meters of concrete. The balance of fuel (~ 11 t), most of which is thought to be located inside the reactor building and sarcophagus, has yet to be positively located (see Table 1 above).

The reactor building itself, especially above the floor of the Central Hall, suffered extensive damage and resulted in the complete destruction of the roof and upper building structures (high bay)—reducing the height of the building from an initial 71.5 m to an average 46 m (Sharovarov, 1990). Other major components, including the ECCS, deaerator system, four steam drum separators, eight MCPs, and primary piping were heavily damaged or destroyed. The explosion's pressure wave significantly displaced those reactor building support columns not completely destroyed, including the 75 m-tall main ventilation stack—compromising the building's structure integrity and seriously complicating the subsequent construction of the “sarcophagus.”

Hot core materials (fuel, graphite, and other components) expelled during the explosions started fires in and around the destroyed unit. Particularly heavy damage was suffered by the roof of the “machine hall” covering ChNPP4's twin 500 MWe turbine generators (TG7 and TG8), which collapsed in many places—causing further side-spread damage to equipment below. Large quantities of flammable seal and bearing cooling oil were located at intervals along the external walls and below the main turbine hall level along the entire 750 m-long “machine hall.”

The initial explosions and fires wafted radioactive materials high into the air, much of which were carried away in the form of gases and aerosols by normal air currents. During the Active Phase of the accident, the Soviets officially estimated a total of 50 MCi of noble gases (100% assumed released) and a total of about 50 MCi of other radionuclides (rough 3.5% of core inventory) were released to the environment (Aleksakhin et al., 1991). The currently accepted total radioactivity releases from Chernobyl are 14,000 PBq or 378 MCi (Devell et al., 1995; IAEA, 2006; Sweet, 1999; Devell and Johansson, 1994)—almost four times that reported by the Soviets. (USSR State Committee on the Utilization of Atomic Energy, 1986). For comparison, approximately 17 Ci of Iodine and 2 MCi of noble gases were released from Three Mile Island Unit-2, roughly 1 MCi total activity released from Windscale, and about 1020 PBq (27.6 MCi) from Fukushima-Daiichi (see Mizokami and Rempe, 2021—updated based on WANO).

As a consequence of these releases, within a few months after the accident over 4 km² of pine forest immediately adjacent to ChNPP reddened, died, were plowed under, covered with fresh soil, and sprayed with dust-suppressing solution (Asmolov et al., 1987). The 1438 km² of land within the 30-km Exclusion Zone was declared unfit for any agricultural activity in perpetuity. Of this, 864 km² are located in Belarus and 574 km² in Ukraine. In addition, 69 km² of tillage and pastureland are contaminated to over 80 Ci/km² of Cs-137, 601 km² between 40 and 80 Ci/km², and 16,670 km² to over 5 Ci/km². For perspective, the Soviet lower-bound standard for land considered “exclusionary and designated for evacuation” is 15 Ci/km² of Cs-137—an equivalent planar mass density of about 1/6th gm/km².

Thirty-six and one-half hours after the accident, evacuation of the 49,614 residents of Prypiat began and was completed within 3 h. By this time, the radiation levels outdoors in the city ranged between 400 and 1500 milliroentgen/h (mR/h). Starting between 2

Fig. 11 Hypothesized accident progression scenario during the active phase (looking north).

Accident clock	Time and/or date	Event(s) description
① 0	~01:26:45 26 April	Explosions destroy core; fuel tubes severed at transition joints; UBS thrown several meters upwards
0 ⁺	~ 01:27 26 April	Pulverized fuel assemblies, control rods, graphite, other core components and debris settle on top of the LBS
② 0 ⁺ → 6.5-7.0	26 April-2 May	Denser, melted, fuel layer forms below graphite and other debris; UO ₂ likely oxidized to U ₃ O ₈ ; fuel corium interacts with LBS steel shell and serpentine filler; upper layer of debris/graphite systematically degrade—forming particulates that serve as mechanical transport path
③ 6.5 → 7.0	02 May	Upper layers of debris and graphite melt or otherwise degrade until corium below exposed—increasing release effectiveness for radionuclides; still unclear what happened to the graphite which does not readily oxidize and is not significantly observed as part of FCMs
④ 7.5 → 8.5	3-4 May	Corium melts through LBS and flows downward into the ALS region—spreading out with declined decay heat and rise in corium solidus—enhancing solidification
⑤ 8.5 → 9.0	4 May	End of Active Phase: releases drop dramatically; corium solidifies in mid-flow; little damage to ALS structures
⑥ >9.0	>5 May	Remaining portion of LBS slowly descends 3.85 m as steel core support structure yields under ~800-900 t load and high temperature-induced creep

and 5 May (6.5–9.5 days after the accident) and extending through August 16, 1986, 90,784 people were evacuated from 75 population centers in Ukraine. By the end of 1986, almost 25,000 people from 107 population centers in Belarus were evacuated. Evacuation of residents from significantly contaminated areas in Russia took up to 3 years, affecting 6805 people in 44 population centers. By the end of 1991 (the time of the collapse of the Soviet Union) approximately 163,000 people had been resettled from Ukraine, Belarus, and Russia, with significant and very expensive evacuation and medical-support efforts continuing for years afterwards (Sivintseva and Kachalova, 1992).

On the night of the accident two Chernobyl plant personnel died, and 28 more persons (operators and firemen) died within a few weeks as a result of acute radiation poisoning—this out of a total of 237 persons originally diagnosed with acute radiation sickness onsite, including subsequent clean-up efforts (to which later 124 more cases were confirmed).

Due to several factors, including the lack of an adequate radiological baseline and the “scattering” of approximately 650,000 workers engaged in accident mitigation efforts (including construction of the sarcophagus), retrospective dosimetry and estimates of deaths attributed to the accident are difficult. Nonetheless, tremendous work has been completed since the accident to assess health effects. UNSCEAR (2012) notes that apart from an increase in thyroid cancers (especially in children), “there is no evidence of a major public health impact attributable to radiation exposure 20 years after the accident.”

Causes and reactions

The accident occurred during a safety experiment (test) to determine adequacy of on-site power during a loss of offsite power. The safety test investigated whether power from spinning-down turbine-generators was sufficient to run the MCPs until the emergency diesel generators could power up. It was an electrical engineering test—one not intended to impact directly any nuclear aspects of the reactor. Similar tests had been attempted at ChNPP3, but power from the spinning-down turbines decreased too rapidly. New voltage regulator designs were to be tested at ChNPP4.

In their January 1993 report, the IAEA’s International Nuclear Safety Advisory Group (INSAG) identified the root technical cause of the accident as the RBMK design and firmly shifted blame away from the operators to the designers (INSAG, 1993). The Group’s original report (INSAG, 1986) based on partial and slanted material provided by Soviet officials in Vienna in August 1986, laid much of the blame on the operators. The design faults identified in the 1993 INSAG report were associated with RBMK features intended to make it a more efficient reactor. The most serious indictment was the revelation that identified design problems had been recognized by the Soviets before the accident.

As discussed below, a confluence of root causes (or precursors), technological and non-technological, led to the destruction of ChNPP4.

Technological causes and corrective actions

Following the accident, a number of contributing technological factors were evaluated to determine root causes. Most broadly these root causes may be classified as (a) inadequate or flawed design, and (b) excessive reliance on administrative controls to fulfill critical safety functions (see Rempe (2021) for discussion of critical safety functions). Indeed, design deficiencies and inadequate training, combined with inadequate safety evaluations and multiple operator errors during a turbine-generator safety test, placed the reactor into an unstable state that led to the accident.

Four design deficiencies, which were identified as technological causes of the accident, are listed below with corrective actions eventually taken by the Soviets to resolve them:

- Positive reactivity insertion for control rods scrambled from an initially fully withdrawn position. To improve the moderation capability of the reactor core and increase effectiveness of control rods, the design incorporated a graphite extension (or “follower”) at the bottom of the rods. However, the “follower” was too short: with rods fully withdrawn, the bottom of the rod channels within the core were filled with water—which in an RBMK acts as a poison. Therefore, the initial displacement of the water with graphite added reactivity to the core (Kurchatov Institute, 1991).

Short-term corrective actions: The graphite followers were lengthened.

- Positive void coefficient is manifested under conditions of relatively high burnup and at relatively low reactor power. The design of RBMKs results in certain low-power operating ranges manifesting over-moderation. In other words, the graphite-moderated RBMKs are “over-poisoned”; the water is more significant as a poison than as a moderator. If water density decreases (e.g., due to boiling-induced voiding), the effect of water poisoning decreases—effectively increasing reactivity.

Short-term corrective actions:

- the number of fixed control rods in the core was increased by 80–90 rods;
- the number of bottom-inserted control rods was increased by 8–16 rods;
- fuel enrichment was increased to 2.4% to compensate for control rod modifications and introduction of additional absorbers (this also increased the potential for higher local peaking factors);
- automatic calculation of operational reactivity margin (ORM) was increased from every 30 min to every 5 min with a control room display provided;

- the limit for the calculated ORM was increased from 26–30 to 43–48 rods.
- changes to identify (using improved analysis methods) and to avoid (using administrative controls and design changes) operating conditions with a large positive steam (void) coefficient of reactivity.
- Slow control rod insertion times. As noted above, typical control rod full-insertion times for LWRs are less than 4 s whereas the insertion time for control rods at ChNPP4 was nearly 20 s.

Short-term corrective actions: (a) the speeds for drive mechanisms were increased to reduce RBMK control rod insertion times to 12 s; (b) a fast-acting automatic emergency protection system which drops 21–24 control rods into the core within 2.5 s was installed.

- Insufficient automatic backup shutdown systems. During the course of the turbine-generator safety test, operators were able to override interlocks several times—including switching off the emergency shutdown system. This imposed a manual rapid-response burden directly upon the operators in their attempt to shut down the runaway power increase.

Short-term corrective actions: in addition to the installation of a fast-acting automatic emergency protection system noted above, double key interlocks were installed to limit operators' abilities to disable emergency protection systems.

Other improvements implemented at RBMKs include the following:

- installation of automated control room displays for disabled protection systems;
- incorporation of interlocks that automatically limit the number of control rods that can be manually withdrawn from the core;
- addition of redundant power supplies for drivers and control circuits of the control rod management system;
- integration of automatic emergency protection shutdown systems under conditions of core coolant low-flow or low-pressure situations;
- improved operational procedures were instituted, including administrative controls to prohibit disconnection of reactor protection systems.

Non-technological precursors

Important societal (historical, ideological, political, cultural, institutional) precursors contributed—not as root or direct causes, but to establishing conditions for an increased likelihood for the accident. Soviet attitudes toward scientific advancement, technological modernization (“nuclear positivism”) and safety were driven by years of ideological commitments, political expediency, and national pride. From its very inception, the Soviet Union paid inordinate attention to the expansion of power production to support the material and technical base of communism as envisioned by Lenin. Compounding this were other factors, including siting considerations near population centers with uneven distribution of water resources, transportation costs, short-cutting environmental concerns, and hard currency generation (primarily through the sale of oil) (Feshbach and Friendly Jr., 1992).

As emphasized by Bernstein and Kushment (1987), “Large-scale engineering systems are more than a collection of technological instruments; they are a reflection of their societies and of the management practices and bureaucratic procedures... Chernobyl and the Challenger explosion had a surprising symmetry in some respects.” The similarities identified included the following:

- the momentum of long-term successful programs;
- military involvement in design objectives and control;
- eventual transition from “mission oriented” to “ordinary repetitiveness”;
- economies of scale spurred “routineness” in shuttle missions and RBMK mass production;
- for the Soviets, adherence to party loyalty through adherence to bureaucratic procedures took precedence over technical ability; for the U.S., the flow of information was compartmentalized.

The Soviets were inheritors of a technocratic progressivism characteristic of the economic policies of capitalist societies prior to when limits on growth and environmental consciousness are imposed. In part, this emerged naturally from Soviet ideological commitments to and a boundless faith in technology and the beneficial effects of technological developments upon mankind's welfare. Soviet nuclear energy policy, in particular, was driven by a desire to demonstrate conspicuous technological achievements in a large-scale program the Soviet Union regarded as urgent to its superpower status. A thriving nuclear power program was seen as a means of enhancing the prestige of the country and providing visible evidence of the superiority of socialism. As emphasized by Josephson (1986), the Soviets developed a cavalier attitude toward safety: nuclear power plants were sited relatively close to population centers for convenience in power transmission, the need for redundant core cooling systems was disregarded, and costly containment structures were eliminated.

An interesting aspect of Soviet society was the unofficial workplace (institutional) practice called *shturn*, or the periodic, frantic attempt to meet plan fulfillment quotas. The most important plant quotas were those imposed by yearly and five-year demands for production. However, there were also quarterly and monthly quotas that became especially important just before State holidays such as the May 1st Socialist Labor Day celebration and vacation period, which informally welcomed the summer period and was second only to the October Revolution celebrations. The importance of this *shturn* period for meeting production quotas cannot be over-emphasized. Indeed, it is quite likely the pressure was great to produce electricity and successfully complete the safety test in order to obtain holiday bonuses. This, in turn, would have influenced workers to inadvertently relax safety practices—a contributing factor to the accident (Medvedev, 1991). Indeed, ChNPP4 operators were anxious to complete the safety experiment because they would lose their bonuses and would not have another chance for over a year... or not at all because another plant

might be requested to complete it. For this reason, operators were not pleased when, after the reactor was dropped to a little less than one-half power (1600 MWt per normal experimental procedure) on 25 April, an additional nine-hour delay was imposed by the grid dispatcher. This was done to support last-minute production quotas for heavy industry prior to May Day. The only thing that seemed to matter was to meet or exceed quotas so that bonuses could be had. The demand imposed by the grid dispatcher was not so much an order by the Ministry of Energy and Electrification as it was haranguing by factory managers to squeeze out as much power as possible prior to the holiday.

The sequence of events, when considered comprehensively, provides a deeply disturbing account of multiple violations driven by political, economic, and personal expediencies... with safety considerations missing in action. There was a lack of emphasis on safety culture, which as noted by Vargo (2000), "refers not only to the defense in depth design but also to the personal responsibility of all of the staff involved in safety-related activities. Implementation of a safety culture means, among other things, that personnel training should place primary emphasis on understanding reasons behind safety practices as well as the safety consequences for failure to adequately comply with personal obligations. Safety culture presumes an overall psychological bias toward safety, as established by organization managers involved in NPP construction and operation."

International reaction: Support for safety upgrades and push for closures

The ChNPP4 accident raised significant concerns among many countries and international organizations regarding the safety of all Soviet-designed reactors (USNRC, 1989; GAO, 2000; IAEA, 1993a,b; PNNL, 1997). These concerns included inadequate means for fire-protection, substandard materials and poor-quality construction, and inadequate separation and redundancy of safety systems. Significant generic RBMK safety issues have been addressed with international assistance based upon safety reviews led by the IAEA, yet skepticism remains. Safety upgrade projects have been sponsored by individual countries (United States, United Kingdom, Canada, Finland, Sweden, Japan, etc.) and international organizations such as the IAEA, the Nuclear Safety Account of the EBRD, the European Union, and the World Association of Nuclear Operators (WANO). Safety upgrade areas included (a) core monitoring and control, (b) instrumentation and control, (c) pressure boundary integrity, (d) accident analysis, (e) safety and support systems, (f) fire protection, (g) operational safety.

A real concern was that another accident at a Soviet and post-Soviet nuclear facility would affect the West directly. First, a major accident would have the potential to undermine the stability of new democratically elected governments, which would be a blow to international efforts aimed at strengthening open markets and free trade. Second, Western investments and aid to former Soviet countries could be placed at risk with potential repercussions on international economies. Third, it would require billions in international assistance to support recovery efforts. And, fourth, such an event could negatively impact the continued viability of nuclear power throughout the world.

A keen interest in developing and strengthening independent nuclear regulatory oversight in former Soviet countries also arose following the accident. Very significant post-Soviet economic-transition difficulties eroded the ability of already weak regulatory bodies to provide adequate safety oversight. In particular, western experts strongly agreed that, among other Soviet-designed reactors, RBMKs fell well below accepted international safety standards and that they could not be upgraded. In particular, there was concern about the lack of a containment structure, inadequate safety systems, insufficient safety backup equipment, unreliable controls on reactor operations, and deficient systems for emergency reactor core cooling.

Soviet-designed reactors were built from a perspective that emphasized power production over safety and assumed timely human interventions would prevent accidents. In contrast, western designs and operations stressed safety over production. This spurred the development of highly automated safety and shutdown systems with minimal reliance on operator involvement. Moreover, because of operational and design priorities, Soviet designers, builders, operators, and regulators did not accept the wisdom of adhering to best international safety practices.

Also, "pride of ownership" on the part of the Russian Federation (expertise in both the design and operation of Soviet-designed reactors was primarily located in Russia during the Soviet period) complicated the situation for newly independent countries emerging from their Soviet past. These countries had to quickly establish their own technical and nuclear regulatory infrastructures. Furthermore, relations between these countries and the Russian Federation deteriorated—exacerbating issues such as the following:

- the difficulty in obtaining replacement parts resulted in makeshift arrangements
- payments to nuclear utilities for electricity production were largely carried out through in-kind markets, sometimes delayed, and often insufficient to cover operational costs—not to mention safety improvement costs
- salaries for nuclear power plant operators were not competitive with other jobs, and salary payments often came late
- regulators earned even less, making the hiring and retention of qualified specialists very difficult.

Indeed, while Chernobyl was the focus, the West took upon itself a mission to assist in reducing risks at Soviet-designed nuclear power plants and to assist host countries in developing a self-sustaining nuclear safety improvement program (operation and regulation) eventually capable of reaching internationally accepted best safety practices without encouraging long-term operation of most risky reactors. The West strongly promoted the importance of safety above all other priorities—to be reflected in the regulation, operation, and professional attitudes of the designers, operators, and regulators of nuclear facilities. The West also pledged to support host countries in the development and strengthening of infrastructure, expertise, and resources in order to participate actively, effectively, and responsibly within the international nuclear power community. That is, relationship-building and enhancement of trust animated western efforts to support and strengthen the technical area goals of operational safety, training, maintenance, safety systems, safety evaluation, as well as legal and regulatory capabilities.

Post-accident shutdown and decommissioning activities

At the time of the accident, 17 RBMKs were operating in Lithuania, Russia, and Ukraine. Since then, the remaining ChNPP Units 1–3 (Ukraine), Ignalina Units 1–2 (Lithuania), and Leningrad Units 1 & 2 (Russian Federation) were closed permanently. Construction on eight units and plans for one unit were cancelled. The Russian Federation currently operates 9 RBMK units at the Smolensk, Leningrad, and Kursk plants with the last unit (Smolensk-3) due to shutdown in 2050 (WNA, 2019a,b).

Following the accident, the situation in and around the ChNPP region was significantly affected. The initial phase involved managing the consequences of the accident, including evacuating the neighboring population. This was followed by a series of daunting tasks, which included restoring power production at the remaining units, cleaning areas where workers had to continue their activities, collecting and storing contaminated wastes spread over the Exclusion Zone, preventing major leakages of contaminants into the water system, encasing the remains of ChNPP4 in a “sarcophagus” designated as “Object Shelter,” (OS) and constructing a new city (Slavutych) to house workers and families evacuated from Prypiat.

Construction of Unit 5 and 6 was abandoned after the accident. During the political changes in the former Soviet Union, the Ukrainian Parliament passed a 02 September 1990 moratorium on the construction of all nuclear power units in Ukraine as well as deciding to eventually close ChNPP. After a major fire in the turbine-generator building in October 1991, Unit-2 was closed and the date for the shutdown of the remaining Units 1 and 3 was fixed by Parliament for the end of 1993. However, the dire economic situation experienced by the country in transitioning from Soviet rule led the Parliament in October 1993 to reverse its original closure decision. Then President of Ukraine, Leonid Kravchuk, also issued a decree in February 1994 requesting restart of Unit-2.

Closing Chernobyl’s remaining Units 1–2 and Ignalina’s Units 1–2 required the combined efforts and support from the Group of Seven (G7) countries, the European Union, and Ukraine, which were implemented through several international programs. The EBRD administers a number of funds under the general rubric of nuclear safety—including the Nuclear Safety Account (NSA) and the Chernobyl Shelter Fund (CSF) which deliver direct, project-based support to Ukraine. In 1995 the NSA initiated nuclear safety projects at Chornobyl—focusing on nuclear safety upgrades and security projects at Unit-3, followed in 1998 by projects to construct two important pre-decommissioning facilities: an Interim Spent Fuel Facility (ISF-2) and the Liquid Radioactive Waste Treatment Plant (LRTP). The CSF was established in 1997 to support the Chernobyl Shelter Implementation Plan (SIP) by assisting Ukraine in transforming the existing sarcophagus into an environmentally safe system known as the NSC + SO (EBRD, 2020).

The West’s early-closure policy developed after the 1992 G7 Munich Summit was directed at the most dangerous Soviet-designed reactors. However, in large part, the policy failed to meet expectations: the “countries in transition” following the collapse of the Soviet Union and Soviet Bloc faced almost insurmountable challenges in reforming their economies. Pressure was applied: as a condition for accession to the European Union for Bulgaria, Slovakia, and Lithuania, eight Soviet-designed reactors were eventually closed. However, 16 reactors of earlier Soviet design (deemed most risky) still operate—including 10 RBMKs in Russia (WNA, 2019a).

In 1994 the G7 Naples Summit proposed an “Action Plan” for helping Ukraine to reform its energy sector that also foresaw the closure of Units 1 and 3 with no restart for Unit 2. Activities comprising the Action Plan included the following:

- Closure of Unit-1 by 1997;
- Decommissioning of Unit-2 without restart;
- Short-term safety improvements to Unit-3, pending its closure by 2000 (IAEA, 1993a,b)
- Provision of facilities necessary to support decommissioning Units 1, 2, and 3;
- Decommissioning of Units 1–3;
- A solution to observed Sarcophagus degradation.

The West applied particular strong political pressure to shutdown ChNPP Units 1 and 3. In December 1994, Nur Nigmatullin, Chief of Ukraine’s nuclear energy utility, *EnergoAtom*, in remarks to G7 representatives reflected the general frustration of countries operating Soviet-designed reactors being pressured to close the most risky reactors—with a barely-veiled barb at the Russian Federation (Sich, 1996a,b)

Of course, we want Chernobyl shut down. What civilized country would want such a reactor? You have no idea what an *ulcer* Chernobyl is for us. But you must understand that in the midst of our current economic crisis, we cannot do so as quickly, inexpensively, and as simply as your governments would like to believe.

On 19 April 1995, then Ukrainian president Leonid Kuchma pledged to close the Chernobyl plant by 2000 if enough resources to do so were provided. In January 2008 the Ukrainian government announced a four-stage decommissioning plan. In February 2014 a new stage of this was approved for Units 1–3, involving dismantling some equipment and putting them into a safe condition by 2028. The plan foresees that by 2046 further equipment will be removed, and by 2064 the units will be dismantled.

Summary—Insights and lessons learned

On April 26, 1986, a safety test led to the most severe accident in the history of commercial nuclear power occurred at Unit 4 of the Chernobyl nuclear power plant (ChNPP4). Root causes of this event, which include reactor design deficiencies, inadequate operator training and plant staff safety culture, are discussed. Over three decades, post-accident recovery measures continue.

Numerous insights were gained and lessons were learned from this accident, related to accident progression and mitigation, RBMK design and operation, and international safety. Some significant insights and lessons, which ultimately enhanced the safety of the operating fleet, are summarized here.

Accident progression and mitigation

- An inextricably linked confluence of root technical causes (design, construction, inadequate training, procedural violations, administrative deficiencies, etc.) and societal/institutional precursors (attitudes, political expediencies, etc.) leading up to and during the safety test destroyed ChNPP4.
- Little to no direct human interventions aided “natural” processes during the Active Phase: the accident stopped itself. During the Active Phase, needed AMAs did not occur and taken actions were ineffective.
- The accident demonstrated conclusively that the postulated “China Syndrome” is impossible—even with a fully melted core exposed directly to the environment.
- The Soviet account of the accident delivered to the IAEA in Vienna 4 months later, not only intentionally misdirected the causes away from fundamental deficiencies in the design (attributing fault solely to the operators) but also misinformed the international community regarding the alleged effectiveness of the AMAs and radioactivity releases (Varley, 1993; Sich, 1996a,b):
- The Soviets did not share post-accident results of investigations with the international community. Only after the dissolution of the Soviet Union did information regarding the progression of the accident slowly emerged strongly countering the initial Soviet account.
- To this day, on the international level, crucial updated information regarding the scope and progression of the accident (doubts about the scope of radioactivity releases soon after the accident and true accounts of the AMAs) remains either ignored or downplayed—muddling not only further appraisals of deficiencies of the RBMK design but also opening the door to popular media myths on both sides of the debate.

RBMK design and operation

- The Soviets knew well before the accident of the potential for serious consequences to arise from design deficiencies and shoddy construction practices.
- The West knew of flawed design and deficient operational issues of Soviet-designed nuclear reactors, and the West also knew of the weak safety culture in the Soviet Union—one that emphasized production over safety (Sich, 2011)
- The effect of the Chernobyl Accident beyond the former Soviet Union accentuated the already significant concerns among many countries and international organizations regarding the safety of all Soviet-designed reactors—leading to a strong effort on the part of the West to pressure for closure of the most-risky reactors and the provision of very significant funds to help upgrade the safety of less-risky Soviet-designed reactors.

International insights

- Chernobyl resulted in changes in the industry’s (within and beyond the USSR) perception about several known challenges:
 - For owners/operators, there was the realization that severe accidents can occur in RBMK designs (there was significant fuel melting and relocation, steam explosion(s), combustion, and significant radioactivity release).
 - Increased recognition of the importance of external stakeholder communication (timely and accurate notifications to domestic and international agencies).
 - The potential for releases from nuclear accidents to transcend national borders (the USSR had to admit what occurred because releases were detected in other countries; other countries became aware of the importance of international nuclear safety).
- Generally, the West understood that no significant design, operational, or regulatory changes would be necessary for their own reactors. For example, the US Nuclear Regulatory Commission (NRC) concluded ChNPP4 lessons fell short of requiring immediate changes in NRC regulations (USNRC, 1989):

Except for the use of a graphite moderator and gravity-driven control rods, these HTGRs (High Temperature Gas-Cooled Reactors and the Chernobyl reactor have no other features in common. The staff assessed the other areas at issue—operations, design, containment, emergency planning, and severe-accident phenomena—and found that the implications of the Chernobyl accident have generated no new licensing concerns for HTGRs and that general conclusion and those pertaining to specific areas are the same as those for light-water reactors. In performing these assessments, the staff reviewed the existing information related to these areas and concludes that programs underway or being considered adequately satisfy any concerns that could be generated because of the Chernobyl accident.

Nevertheless, the NRC staff identified and acted upon several lessons learned from the ChNPP4 accident. In USNRC (1989), the staff identifies several areas of concern, such as low power and shutdown risk, appropriate fire protection measures, and operator training. For example, there was increased recognition of conditions in which positive reactivity coefficients can occur in LWRs:

- In a BWR, unvoided, lower temperature conditions may approach over-moderation when few control rods are inserted.
- In a PWR, a decrease in moderator density results in a decrease in core boron, which, under some conditions, may give rise to a positive moderator coefficient.

The conditions in which this can occur are limited and when present, there is limited reactivity insertion. In addition, LWRs have fast acting scram systems. However, efforts have been made to understand, document, monitor, and take appropriate actions for such conditions, such as modifications to Instrumentation and control systems to detect and suppress instabilities, procedures, administrative controls, and training to ensure that operators understand the issue. In addition, there was increased emphasis on the importance of documenting and sharing lessons from events that had previously occurred in other plants.

- Internationally, there was significantly increased international engagement in existing organizations, such as the Organization of Economic Cooperation and Development (OECD) and International Atomic Energy Agency (IAEA), increased activities to provide nuclear safety support; international conventions on nuclear safety (emphasizing independent regulatory bodies, operator responsibilities, early notification, international system on severity (including development of the INES scale), liability amounts were increased by Paris and Vienna and adopted. An international industry organization, the World Association of Nuclear Operators (WANO) formed in 1989 that offers peer review, performance analysis, member support, and training and development.

Glossary

Beyond Design Basis Event (BDBE) An event less frequent than and with potentially more severe consequences than a design basis accident.

Design Basis Accident (DBA) Accident conditions against which a facility is designed according to established design criteria, and for which the damage to the fuel and the release of radioactive material are kept within authorized limits.

Extended loss of all AC Power (ELAP) An event sequence that results in the failure of all AC power sources at the reactor facility so that only the reactor facility's battery power is available.

Moment of Magnitude Scale A measure of an earthquake's magnitude ("size" or strength) based on its seismic moment. It is expressed in terms of the magnitudes of the original "Richter" magnitude scale.

Introduction

On March 11, 2011 at 14:46(GST+9), the Great East Japan Earthquake (GEJE) and a subsequent tsunami occurred as a result of the seismic slip-rupture, whose length was more than 500 km in the rim of Pacific plate. The moment magnitude scale for the GEJE was evaluated as 9.0. A seismic scram signal was immediately activated at Fukushima Daiichi Nuclear Power Station (FDNPS), which includes six Boiling Water Reactors (BWRs). Units 1, 2, and 3, which were operating at their rated power level, were automatically shut down. Units 4, 5, and 6 were in periodic inspection outages at the time of the earthquake. Due to the collapse of the transmission line tower, FDNPS lost off-site power. However, the emergency diesel generators (EDGs) started, and the electric power necessary to support the required safety systems for the reactors was maintained. Later, a tsunami of up to 15 m in height (well above the design flooding height of 6 m) inundated the FDNPS at about 15:37 (GST+9), flooding electrical equipment such as the EDGs. Accident response measures were hindered by the loss of off-site power and the EDGs, along with a loss of DC power due to batteries being rendered inoperable by flooding or by running out of energy due to extended use. This hindered the ability of operators to monitor the reactor and cooling operations in the main control room.

Plant design

As noted above, FDNPS included six units, designated 1F1 through 1F6 in Fig. 1. Unit 1, which is a BWR/3 design housed in a Mark I containment, is rated at 460 MWe and began operation in 1971. Units 2 through 5, which are BWR/4 designs housed in Mark I

Fig. 1 Fukushima Daiichi Nuclear Power Station. Between each numbered unit is a shared venting tower. Courtesy of TEPCO Holdings.

containments, are rated at 784 MWe. Unit 6, which is a BWR/5 design housed in a Mark II containment, is rated at 1100 MWe and began operation in 1979. For decay heat removal, the earlier Unit 1 design included an Isolation Condenser (IC) system rather than the Reactor Core Isolation Cooling Systems (RCICs) present in Units 2 through 6 [See [Hamon \(2021\)](#) for additional details regarding BWR system design differences].

Accident progression and endstate at Units 1, 2, and 3

While the accident progression differed among the units, the loss of DC power resulted in severe accidents in Units 1, 2, and 3. **Fig. 2** compares the estimated endstate of the reactor building, water, and fuel containing materials in Units 1, 2, and 3 ([Mizokami, 2019](#)). These interim endstate figures, which were developed in December 2018, are based on information obtained from muon tomography and robotic investigations, dose surveys, systems analysis code evaluations, and plant instrumentation data. As additional investigations are completed, these images will be updated.

Unit 1

Unit 1 lost AC and DC power at almost the same time after the tsunami arrived. Because the protective door facing seaside of the turbine building was kept open after the earthquake, a massive amount of tsunami water entered the turbine building. The switchgears were located near the front of this door, and their function was lost soon after the tsunami intrusion. Then, the DC batteries located on the basement floor were lost due to flooding. **Fig. 3** ([Hara, 2017](#)) presents a schematic showing the availability of systems and components after the tsunami inundated Unit 1 at 15:36 on March 11, 2011.

After the reactor tripped due to the seismic accelerations, the operators tried to establish cold shutdown (defined by TEPCO to occur when reactor cooling-water temperature falls below 100 °C) in Unit 1 by removing decay heat and controlling the system pressure by cycling the isolation condenser (IC) on and off within prescribed limits. In the normal shutdown procedure, it is required to control the pressure to ensure a gradual temperature decrease of 55 °C per hour. At the time when AC/DC power was lost, the IC was not in operation and DC power was needed to restart the IC. Therefore, Unit 1 lost its cooling function for about 1 h after the earthquake. The loss of cooling resulted in a decrease in the Reactor Pressure Vessel (RPV) water inventory due to evaporation by decay heat. Fuel assemblies and support structures experienced heat up and exposure to high temperature steam, resulting in hydrogen generation due to vapor–cladding zirconium chemical reaction. By 14:30 on March 12, 2011, Unit 1 was experiencing a severe accident with core damage, core melt, and radioactive material release. Venting actions by the operators (see **Fig. 4**) which were confirmed at 14:30 on March 12, lowered the Primary Containment Vessel (PCV) pressure and radioactive releases were scrubbed by suppression chamber (SC) water. However, the hydrogen explosion at ~15:36 on March 12, and images of the Unit 1 reactor building (see **Fig. 5**) ([TEPCO, 2011a](#)) suggest that PCV boundary failure already occurred, allowing hydrogen to leak from the PCV and accumulate in the reactor building causing the observed explosion.

Unit 1 lost cooling earlier than Units 2 or 3, and the restart of water injection was later. Therefore, it is estimated that damage to Unit 1 is the most severe among the three operating units. The investigation results obtained by muon tomography measurements ([TEPCO, 2015](#)) indicate that almost all the fuel material relocated from the original core location, and analyses predict that molten

Fig. 2 Interim endstate figures (based on December 2018 update) for Units 1, 2, and 3. Courtesy of TEPCO Holdings; Mizokami S. 2019. Current Status and Recent Investigation Result of Fukushima Daiichi. Presented at 9th Conference on Severe Accident Research (ERMSAR 2019), March 2019.

core materials slumped from the RPV to the primary containment vessel (PCV), ablating PCV floor concrete. Images and dose survey information obtained using robots (Fig. 6) (TEPCO Holding, 2017j) and results from water sample evaluations confirm that fuel containing material (FCM) relocated from the RPV with accumulated deposits heights from 20 cm to 100 cm observed external to the pedestal region of the PCV (TEPCO Holdings, 2017i). At present (July 2019), there are no images from robotic examinations inside the pedestal. However, it is estimated that the debris and other materials accumulated similarly to what has been observed in Unit 3.

Unit 2

Unit 2 also lost AC and DC power at about the same time after the arrival of the tsunami. Although one Unit 2 EDG was air cooled and located in a separate building - the common spent fuel storage building, flooding of switchgear in the basement floor of this separate building resulted in the loss of AC power at Unit 2. Fig. 7 presents a layout of the FDNPS plant systems and components and indicates the availability of Unit 2 systems and components after the tsunami inundated the plant on March 11, 2011.

Fig. 4 Unit 1 venting (at 14:39 on March 12, 2011). Note plume from the Units 1 and 2 shared venting stack. This picture is provided by Ishikawa Bon.

After the reactor tripped due to seismic accelerations, operators took actions to place Unit 2 in cold shutdown by removing decay heat and controlling the RPV water level by injecting water using the Reactor Core Isolation Cooling (RCIC) System. The RCIC turbine pump is driven by steam so that it is required to keep RPV water level within a certain range to maintain high steam quality. Although the RCIC system was automatically tripped due to high RPV water level at 14:51 (GMT+9) and 15:28 on March 11, 2011, the RCIC system was manually restarted 15:39 just 2 min before loss of DC power. The RCIC system relies on DC power for critical functions, such as controlling the water injection rate, activating its trip logic sequence, cooling the lubricating oil, etc. It is not fully understood why the RCIC system continued to operate and cool the RPV until the morning of March 14, 2011. Conditions in Unit 2 were outside the RCIC system design envelop, but it continued to operate with low quality steam, high back pressure, and high temperature lubricant oil. It is also not understood what ultimately caused the RCIC system failure.

After loss of the RCIC system, the RPV water level gradually decreased. At about 18:00 on March 14, 2011, the operators depressurized the RPV by opening the Safety Relief Valves (SRVs). The RPV water level at that time was near the top of active fuel (TAF), so the fuel had not yet heated up. When the system pressure suddenly lowered, the water inventory decreased due to flashing; RPV water level suddenly decreased from near the TAF to below the bottom of active fuel (BAF). Thus, the fuel heated up by decay heat rather than interactions between steam and cladding. Water injection from a fire truck should have been conducted just after depressurization; however, injection was delayed due to a lack of fuel for the fire truck. When water was injected onto the preheated fuel assemblies, the exothermic chemical reaction between steam and zirconium-containing cladding generated significant amounts of heat. Thus, Unit 2 experienced a severe accident with core damage, core melt, and radioactive material release on the night of March 14, 2011.

Fig. 5 Unit 1 explosion (at 15:36 on March 12, 2011); (A) image when plume was largest (hiding the reactor building) and (B) damage to the reactor building. (A) This picture is provided by Fukushima Central Television Company 2019. Y. Sakurai, General Manager, News Department, Fukushima Central Television Company, Ltd; (B) TEPCO 2011a Unit 1 of Fukushima Daiichi Nuclear Power Station, photo collection. <https://photo.tepcoco.jp/en/date/2011/201103-e/110313-01e.html>, uploaded march 13, 2011, last accessed July 1, 2019. [used image: 110313_1f_1]).

The Unit 3 hydrogen explosion that occurred at noon on March 14, 2011 hindered efforts to vent Unit 2, failing the valve of the venting line. Therefore, PCV venting was not conducted, but high pressures and temperatures within the PCV are believed to have led to seal degradation, and the PCV pressure decreased on the morning of March 15, 2011. Because releases were not reduced by suppression water scrubbing, Unit 2 released more radioactive materials to the environment than earlier releases from Units 1 and 3.

As shown in Fig. 8, the Unit 2 reactor building was not damaged by any hydrogen explosion. Post-accident evaluations indicate that the absence of any hydrogen explosion was due to “unintentional” early venting of the reactor building. In other words, the Unit 1 explosion at 15:36 on March 12, 2011 (Fig. 5) caused the blowout panel to open, releasing steam and possibly hydrogen. There was no hydrogen explosion within the Unit 2 reactor building. However, it is estimated that the amount of the radioactive materials discharged from Unit 2 is largest among the three units.

Quantification of the generated energy by chemical reaction during core heat up is important to estimate the fuel damage and endstate distribution of FCM in the RPV and PCV. However, there is much uncertainty in the amount of steam available during core heat up because it depends on the amount of water injected by the fire truck. Images obtained using muon tomography measurements (TEPCO Holdings, 2017f) show little damaged or melted material in the original core position with more relocated materials at the bottom of the RPV. Images from robotic investigations show considerable holdup on cabling beneath the RPV, thermally—induced damage to structures beneath the vessel and accumulation of previously molten materials deposited on the PCV floor (with heights ranging from 40 to 70 cm) (TEPCO Holdings, 2018b). As shown in Fig. 9 (TEPCO Holdings, 2017a,e, 2018a), the tie handle from the upper part of a fuel assembly can be seen on the surface of the PCV floor.

Unit 3

Fig. 10 presents a schematic of Unit 3 systems and components available after the tsunami inundated the plant on March 11, 2011 (the layout and floor elevations are similar to that shown in Fig. 6A for Unit 2). Although Unit 3 lost AC power at the time of the tsunami arrival, it didn’t immediately lose DC power because the batteries were at a higher elevation that wasn’t inundated by tsunami flooding. This allowed the operators to initially rely on the RCIC system and when the batteries were depleted, the High Pressure Coolant Injection (HPCI) system.

After reactor trip due to seismic scram, operators worked to place the unit in cold shutdown by removing decay heat and controlling the RPV water level using the RCIC system. The RCIC system continued to operate using DC power until 11:36(GMT+9) on

Fig. 6 Unit 1 robotic investigation. Courtesy of TEPCO Holdings 2017j Unit 1 Primary Containment Vessel Internal Investigation. http://www.tepco.co.jp/en/nu/fukushima-np/handouts/2017/images/handouts_170327_01-e.pdf, last accessed March 2018.

March 12, 2011. It is estimated that the RCIC system tripped when the back pressure reached the trip setpoint (TEPCO Holdings, 2017b). After RCIC system trip, the HPCI system automatically started due to RPV water level decrease. The HPCI system was able to inject water and depressurize the RPV. At 20:36 on March 12, the RPV water level gage data became unavailable due to loss of DC power. The water injection rate by the HPCI system under low pressure was insufficient, and the RPV water level gradually decreased. At 2:42 on March 13, 2011, the operator manually terminated the HPCI system. At this time, the RPV water level had already decreased to the TAF, and the HPCI was stopped to allow low pressure injection using the Diesel Driven Fire Pump (DDFP). However, the SRV failed to open, resulting in an increase in the RPV pressure and a loss of any cooling. Unit 3 fuel assemblies exposed to steam started to heatup, leading to a severe accident with core damage, melting, and radioactive material release. PCV venting through the suppression chamber wetwell with water scrubbing of radioactive material was conducted at around 9:10 on March 13, 2011 (see Fig. 11).

A hydrogen explosion occurred in Unit 3 at 11:01 on March 14, 2011 (see Fig. 12) (TEPCO, 2011c). Post-accident investigations indicate that the Unit 3 hydrogen explosion obstructed recovery actions for water injection and venting at Unit 2. Furthermore, post-accident evaluations found that Unit 3 venting allowed combustible gases to flow through the standby gas treatment system (SGTS) piping and cause a hydrogen explosion in Unit 4 (TEPCO, 2016).

Examinations indicate that core damage incurred at Unit 3 is less than Unit 1 but more than Unit 2. Evaluations indicate that core heat up occurred during the phase where RPV water level was decreasing. Therefore, the Unit 3 endstate is similar to Unit 1. Results obtained by muon tomography measurements (TEPCO Holdings, 2017f) indicate that no large pieces of damaged or previously molten fuel material remain in the original core location and suggest the possibility that some FCMs have relocated to the bottom of the RPV. Investigations by a submersible robot (see Fig. 13) (TEPCO Holdings, 2017g,h) show that a large amount of previously melted materials relocated to the PCV floor with an accumulated height of more than 2 m (TEPCO Holdings, 2018c). Several Control Rod Guide Tubes (CRGTs) and a speed velocity limiter of the control rod, which were initially within the RPV, were identified in the debris bed on the surface of the PCV floor.

Fukushima Japan Accident and Current Situation. Presentation at MIT Nuclear Plant Safety Course, June 21, 2017.

Long term effects on health and nuclear power

TEPCO estimates (World Nuclear Association, 2016) indicate a total of about 1020 PBq was released to the atmosphere between March 12 and 31, 2011. After this time, very little additional radiation was released. Apart from noble gases, this release was comprised of 500 PBq Iodine-131, 10 PBq Cs-137, and 10 PBq Cs-134. Of the total release, it is estimated that about 20% came from Unit 1, 40% from Unit 2 (which peaked on 15 March), and 40% from Unit 3 (which peaked on 16 March). Relatively little radioactive material was released by venting (because it was routed through steam and water before it was released through the exhaust stacks) or by the hydrogen explosions. Based on measurements of residents and evacuees, Tokonami (2012) reports that the median thyroid equivalent dose is 4.2 and 3.5 mSv for children and adults, respectively, and that maximum thyroid doses to

Fig. 8 Steam (and possible hydrogen) release from the Unit 2 building with an open blowout panel. Courtesy of TEPCO Holdings 2017b The 5th Progress Report on the Investigation and Examination of Unconfirmed and Unresolved Issues on the Development Mechanism of the Fukushima Daiichi Nuclear Accident. https://www7.tepco.co.jp/newsroom/press/archives/2017/1485273_10469.html, December 25, 2017, last accessed July 2019.

children and adults were 23 and 33 mSv, respectively. This is much smaller than the average thyroid dose in the Chernobyl accident (490 mSv in evacuees) reported in [UNSCEAR \(2008\)](#).

Radiation released from the affected reactors at FDNPS exceeded official safety guidelines, but there were no immediate deaths caused by these releases. None of the six FDNPP worker deaths were due to radiation exposure ([UNSCEAR, 2014](#)). Given the uncertain health effects of low-dose radiation, cancer deaths cannot be precluded. The United Nations and World Health Organization studies ([UNSCEAR, 2014](#); [WHO, 2013](#)) indicate that no discernible increase in the rate of cancer deaths is expected ([UNSCEAR, 2014](#)). Several deaths, however, are attributed to the evacuation and subsequent long-term displacement caused by the nuclear disaster.

The ultimate impact on the nuclear enterprise is still unknown. All 60 reactors within Japan were shutdown after the accident. Prior to restarting, plants are now required to pass a safety review by the regulator and gain consent by local governments that would be affected by the plant's operation. At the time that this chapter was written, only 9 PWRs are operating and 25 are either being or are set to be decommissioned ([JAIF, 2019](#)).

Lessons learned /impact of post-accident investigations

Uncertainties remain regarding the events after the GEJE earthquake at FDNPS. As post-accident and recovery efforts continue, more information will be obtained regarding the accident progression at each of the affected reactors. Nevertheless, information available from these reactors already provides many lessons for enhancing the safety of nuclear power plants worldwide. This section identifies some of the actions taken or underway by the nuclear industry and regulators to address lessons learned from the events at FDNPS.

Containment venting and filtration

Available instrumentation data and dose survey information indicate that the three operating FDNPS units experienced PCV leakage, but there are uncertainties regarding the actual leakage locations and the timing of such leakages. Many countries have or are in the process of implementing revised severe accident guidance that places a high priority on early venting to ensure that the primary containment is maintained at pressures and temperatures well below values that challenge containment integrity ([Aleza, 2018](#); [Steinrötter, 2018](#); [O'Neill, 2018](#); [Duspiva, 2018](#); [TEPCO Holdings, 2017b](#)). As discussed in [Lutz and Williamson \(2021\)](#) containment performance will be enhanced in the United States by anticipatory venting using the hardened vent systems mandated for Mark I and Mark II BWRs ([NEI, 2015](#)). In some countries, measures are being considered to add or upgrade filtered containment venting systems for CANDU, PWR, BWR, and VVER units as a severe accident mitigation strategy. However, there are reservations regarding their effectiveness and reliability, as well as the instrumentation required to support such systems (e.g., [LaBarge, 2018](#); [Steinrötter, 2018](#); [Cenerino, 2018](#)).

Severe accident water addition

Available information (see [Fig. 2](#)) indicates there are differences in the debris end-states at Units 1, 2, and 3. These differences stem from differences in their accident progressions which were affected by the availability of water for cooling. Many countries have

implemented measures regarding water addition based on insights from FDNPS (NEI, 2015; Steinrötter, 2018; TEPCO Holdings, 2017b). As discussed in Lutz and Williamson (2021), revised US BWROG guidance based on examination information includes severe accident water addition and water management strategies to enhance the effectiveness of fission product scrubbing in the suppression pool during venting through the hardened vent system. The PWROG guidance also includes water addition (possibly via containment spray operation for fission product mitigation) during venting. The guidance considers the impact of water addition on containment integrity and contains guidelines for venting during water addition to prevent over-pressurization of the containment.

Infrastructure degradation

Recovery efforts at FDNPS were hindered by damage to on-site and off-site infrastructure. The loss of all on-site and off-site power along with the inability to bring replacement equipment to the site due to traffic disturbances, such as road damage from the earthquake, hindered the ability of plant staff to restore cooling to the reactors and spent fuel pools at Daiichi. To address such challenges, additional measures have been implemented in many countries (LeBerge, 2018; O'Neill, 2018; Gilbert, 2018a; Gilbert, 2018b; Patel, 2018; Steinrötter, 2018; Suslov, 2018; TEPCO Holdings, 2017b; NEI, 2016) to ensure that there is additional equipment on-site and in some cases, to ensure that additional equipment can be transported on-site even when roadways may not be available. For example, the US industry has instituted the FLEX program that requires that all plant sites maintain additional

equipment for water injection, power restoration, and debris removal as well as similar equipment that are maintained at two national response centers for transportation to plant sites (NEI, 2016). Within Japan, similar measures have been instituted to ensure that such equipment is available to plant sites (Masui, 2019). New requirements, which were instituted by the newly formed Nuclear Regulatory Authority (NRA), also include measures such as enhanced radiation monitoring, effective communication with local governments as well as domestic and international agencies, strengthened emergency response capabilities, consideration of common-cause failures due to fires, flooding, or large scale disasters, and adoption of safety goals (NRAJ, 2011, 2013, 2017).

[Used image: 110321_1f_kokuen1]

Multi-unit effects

The events at FDNPS highlighted the need to assess a multi-unit site against multiple concurrent and correlated hazards. There were some advantageous multi-unit effects. For example, even though Unit 5 lost its EDGs, one of the surviving DGs at Unit 6 was available to supply AC power to a neighboring facility, Unit 5 (TEPCO, 2012). In addition, the Unit 1 explosion precluded an explosion within the Unit 2 building due to "unintentional venting". However, most multi-unit effects were disadvantageous. The Unit 3 hydrogen explosion delayed recovery actions at Unit 2, and Unit 3 venting allowed combustible gases to flow through the SGTS piping and cause a hydrogen explosion in Unit 4. Actions to eliminate the potential for backflow in SGTS piping and emphasize early PCV venting address some of the observed adverse multi-unit effects (TEPCO Holdings, 2017b; NEI, 2015). In addition, several countries have re-evaluated, and if needed, implemented enhancements to systems for detecting and mitigating the effects associated with hydrogen accumulation (e.g., see Gilbert, 2018a). Finally, the multi-unit effects observed at FDNPS have increased awareness of the need to consider multiple sources of radiation release; the new FLEX equipment is designed to ensure that there are backup systems to provide power and cooling to protect the integrity of fuel in each reactor and spent fuel pool at a site (NEI, 2016; Gilbert, 2018a; Desaulniers, 2018).

Component and system performance under beyond design basis conditions

Several systems and components, such as the RCIC and IC systems and selected plant instrumentation, were able to survive under beyond design basis conditions at FDNPS. Post-accident investigations have provided some insights regarding the performance of such systems and components (TEPCO Holdings, 2017b), but additional information is desired. For example, a joint US-Japan effort is underway to test RCIC systems under beyond design conditions to determine if it is possible to gain regulatory credit for RCIC system performance, and results from evaluations of plant instrumentation have been incorporated into revised US BWROG guidance for severe accident conditions (Rempe et al., 2019). In addition, several countries have or are considering additional instrumentation for detection and mitigation of severe accident conditions (Cenerino, 2018; TEPCO Holdings, 2017b).

Up-to-date comprehensive assessments of external hazards

The events and associated consequences of the events at FDNPS underline the need to assess the potential for external hazards and combinations of such hazards. In recent years, there have been several other examples of flooding or seismic events that exceed those considered within a site's design basis such as the 1999 flooding event in the Blayais Nuclear Power Plant in France and the 2011 seismic event at the North Anna plant in the United States. After the events at FDNPS, the need for updated assessments of external events received increased attention. At this time, updated evaluations have been completed in several countries; and where warranted, additional measures to address increased challenges have been taken (NEI, 2015; O'Neill, 2018; Duspiva, 2018; Patel, 2018).

Fig. 13 Investigations through the Unit 3 X-6 penetration revealing lower end of relocated control rod. Courtesy of TEPCO Holdings 2017g Unit 3 Primary Containment Vessel Internal Investigation. http://www.tepco.co.jp/en/nu/fukushima-np/handouts/2017/images/handouts_171130_03-e.pdf, November 30, 2017, last accessed July 2019; TEPCO Holdings 2017h Progress of unit 3 PCV internal investigation(1/2)(preliminary report of July 19 investigation). http://www.tepco.co.jp/en/nu/fukushima-np/handouts/2017/images/handouts_170719_01-e.pdf, July 19, 2017, last accessed July 2019.

Importance of regulatory independence and safety culture

As discussed by Rempe and Williams (2021), the events at FDNPP emphasized the importance of regulatory independence and safety culture. Prior to the Fukushima Daiichi accident, the primary Japanese regulatory agency, Nuclear and Industrial Safety Agency (NISA), was part of the Ministry of Economy, Trade and Industry (METI), which was responsible for regulation and promotion of nuclear energy in Japan. Following the Fukushima Daiichi accident, NISA's association with METI was believed to have compromised its independence. As emphasized in Rempe and Williams (2021), the establishment, implementation, and maintenance of a robust nuclear safety culture is dependent on a technically strong and independent regulator. Several reports (Government of Japan, 2011a,b; NAAIIC, 2012) indicate that NISA failed to monitor or supervise nuclear safety and had lost its technical expertise. Hence, the regulator was not independent and subject to regulatory capture. TEPCO also acknowledges that the reluctance to enhance plant safety against external events using a "step-by-step process" contributed to the severity of the events at Daiichi.

To address these issues, the Government of Japan (NRAJ, 2011, 2013, 2017) reorganized the regulatory framework and established a new regulator independent of METI, the Nuclear Regulatory Authority (NRA) as part of the Environment Ministry. The NRA is responsible for promulgating rules and regulations for nuclear plants and evaluating whether current Japanese plants can resume operations (Approval from local governments is also required prior to plants being allowed to resume operations in Japan). Following its inauguration on September 19, 2012, the NRA carried out a complete review of safety guidelines and regulatory requirements and developed a set of new regulations to protect people and the environment. The new regulations consider the

lessons learned from the events at Fukushima Daiichi, updates regarding harsh natural conditions unique to Japan, and current international safety standards and guidelines. On July 8, 2013, the new regulatory requirements for commercial power reactors were enforced. However, a five-year deferment period is allowed for implementing some safety measures, such as the use of filtered venting systems in PWRs.

Summary

As evidenced by these examples, many actions have already been taken to address insights from the events at FDNPS. As defueling efforts continue, additional insights will be gained, which are of interest to the international community for enhancing the safety of the global nuclear enterprise.

Glossary

Advisory Committee on Reactor Safeguards (ACRS) Independent advisory committee to the U.S. Nuclear Regulatory Commission (NRC) that is statutorily mandated by the Atomic Energy Act of 1954, as amended.

Criticality The normal operating condition of a reactor, in which nuclear fuel sustains a fission chain reaction. A reactor achieves criticality (and is said to be critical) when each fission event releases a sufficient number of neutrons to sustain an ongoing series of reactions.

Defense-in-Depth (DiD) A design and regulatory principle that relies on several consecutive and independent levels of protection that would have to fail before harmful effects could be caused to people or to the environment. If one level of protection or engineered barrier were to fail, the subsequent level or barrier would be available. When properly implemented, DiD ensures no single technical, human or organizational failure could lead to harmful effects and the combinations of failures that could give rise to significant harmful effects are of very low probability.

Design Basis Accident (DBA) One category of the postulated accidents used to set criteria and limits for the design and sizing of safety-related systems, structures, and components.

Design Basis Event (DBE) An event considered in the range of conditions, including normal operation, DBAs, and natural phenomena, for which the plant must be designed to ensure acceptable performance of structures, systems, and components.

Emergency Core Cooling System (ECCS) A separate and independent cooling system for the reactor core in the event of a "loss-of-coolant accident".

Engineered Safety Feature (ESF) A system, structure, or component relied upon during or following a DBE to prevent or mitigate the associated consequences from such an event.

Final Safety Analysis Report (FSAR) Document, submitted by an applicant, providing information to support the NRC safety evaluation of a proposed facility. It is based on the finalized detailed design of the facility, and it must periodically be updated throughout the life of the facility.

General Design Criteria (GDC) The set of minimum requirements for the design and safety analysis of water-cooled nuclear power plants.

Reactivity A measure expressing the departure of a reactor system from criticality. A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

Safety-Related Equipment Systems, structures, and components relied upon to remain functional during and following DBEs. Their functionality ensures key regulatory criteria, such as levels of radioactivity released, are met.

Safety Margin In engineering, the difference between the predicted value for a parameter and the value at which failure occurs. In the nuclear industry, safety margins are ensured by setting a conservative safety limit for a parameter and maintaining conditions below this limit by an amount that is at least commensurate with the uncertainty in predicted values for this parameter.

Single Failure Criterion The criterion that no single technical, human, or organizational failure should lead to undesirable consequences. In reactor design, the criterion that the failure of a single system or piece of equipment will not adversely affect public health and safety.

Introduction

From the onset, it was recognized consequences of accidents from a nuclear power plant could have more impact than other types of industrial accidents. As noted by Smyth (1945) in his efforts to design a plant for production of plutonium: “The problem of dissipating thousands of kilowatts of energy is by no means a small one.” To assure safety functions within a nuclear power plant are maintained, Garrick (2013) emphasizes two fronts — the design of the physical system and the evaluations of the physical system design.

On the physical system front, designers emphasize inherent features, such as negative moderator temperature reactivity feedback, which causes an overall decline in reactor power when the moderator temperature increases. Remote plant siting provided additional protection of the public. Designs incorporated independent, redundant, and diverse barriers, such as a containment building, and independent, redundant, and diverse systems to provide emergency core cooling and backup electric power. With time, commercial nuclear power plant designs evolved, not only to maximize economics but also to enhance safety. The need for additional safety measures to address new challenges was illuminated by events, such as the Browns Ferry Fire and the Salem Anticipated Transient without Scram (ATWS) events without core damage (Rempe, 2021) and the Three Mile Island Unit 2 (Skillman and Rempe, 2021), Chernobyl Unit 4 (Sich, 2021), and Fukushima Daiichi (Mizokami and Rempe, 2021) events with core damage. Additional safety measures have been incorporated into the spectrum of nuclear power plant activities, including emergency planning, siting criteria development, design, manufacturing, construction, commissioning and operation, as well as decommissioning and closure.

On the evaluation front, the critical role of safety analyses has been emphasized throughout the development and deployment of commercial nuclear power plants. Results from safety evaluations have been compared with acceptance criteria to assess the ability of barriers and equipment to provide critical safety functions during normal and off-normal (accident) conditions. After events with core damage occurred, it became clear such evaluations required a better understanding of their likelihood of occurrence. Worst-case and maximum-credible accident evaluations were no longer sufficient for ensuring plant safety. Everyday transients, followed by multiple failures of equipment and mistakes by operators, were more likely to occur than the hypothetical design basis accidents required for licensing. Hence, the use of more realistic evaluations and probabilistic risk assessment (PRA) became important in assuring critical safety functions were maintained.

This chapter provides an overview of areas important to ensuring reactor safety by design and evaluation, highlighting the topics of critical safety functions, defense-in-depth (DiD), and regulatory framework. In addition, an example is provided to illustrate that results from evaluations can affect the design of reactor systems and the regulatory framework. Additional information related to reactor systems, operator guidance for prevention and mitigation of accidents, and evaluation of plants with such systems and guidance is found in Lutz and Williamson (2021a,b,c,d,e) and Gauntt (2021).

Critical safety functions

Nuclear power plant safety is assured by maintaining three key reactor safety functions: control reactivity, control cooling, and control radioactivity release (see Fig. 1). Several references (WANO, 2019; IAEA, 2016) emphasize these three “Critical Safety Functions” must be preserved during normal operation and accident conditions. Some references provide a more extensive list; for example, the function to control release of radioactive materials may be separated into functions performed by individual barriers (e.g., the reactor vessel and the containment) or the function to control cooling may be separated into different cooling functions (e.g., maintain core cooling, maintain containment cooling, and maintain the coolant heat sink). However, such additional functions can be consolidated into the three critical safety functions depicted in Fig. 1.

These functions guide reactor design, and evaluations are performed to assess the adequacy of the design to ensure these functions are maintained. Critical safety functions also play an important role in selecting design basis events, events considered in PRAs,

Fig. 1 Critical safety functions.

safety-related equipment, and the minimum number of plant parameters that should be monitored. For example, there are several standards by the American National Standards Institute (ANSI) and the American Nuclear Society (ANS), such as ANSI/ANS 58.14-2011 (ANS, 2017), that stress the importance of these critical safety functions in evaluating the performance of safety-related components. Reviews of prior events with significant core damage at commercial nuclear power plants (see Skillman and Rempe, 2021; Sich, 2021; Mizokami and Rempe, 2021) emphasize root causes associated with one or more of these critical safety functions not being maintained. Risk assessments (Modarres and Kim, 2021) often classify accident progressions in terms of safety function failures. As discussed in Lutz and Williamson (2021d,e), the need to ensure “critical safety functions” underlie development of “symptom-based” procedures. By relating these safety functions to specific plant/control room instrumentation, operators can monitor a relatively few pieces of information to ascertain the plant status.

After the success of initial prototype demonstrations, designers explored several options to make nuclear power production more economical (Walker, 1992; Mazuzan and Walker, 1997; Okrent, 1981). One option was to build larger generating plants, decreasing the number of sites, foundations, control rooms, auxiliary equipment, and other expenses required to complete an individual power plant. Another option was to lower transmission costs, locating plants nearer to residential areas. To ensure critical safety functions were preserved with these economic benefits, designs were required to include additional safety measures, such as engineered safety features (ESFs) and instrumentation to monitor the status of these ESFs. Today, there is a combination of preventive measures to avoid accidents and mitigating measures to decrease the adverse consequences of accidents that cannot be prevented.

Defense-in-depth (DiD)

As discussed in Rempe and Williams (2021), a DiD principle is applied in reactor design, and evaluations are completed to provide confidence the design incorporates adequate measures to maintain critical safety functions. The DiD principle requires a combination of several consecutive and independent levels of protection (barriers) fail before any harmful effects to people or the environment occur. Levels of protection include a combination of factors, such as remote site selection, ESFs, safety margin in design, diverse and redundant protection systems, operating procedures and practices, management commitment to safety and security, and a robust nuclear safety and security culture. This principle is also applied in evaluations of external hazards and severe accidents. No single technical, human, or organizational failure should lead to an uncontrolled release of radioactivity (often referred to as the single failure criterion). When properly implemented, the DiD principle ensures the combination of failures that could give rise to significant harmful effects has a sufficiently low probability of occurrence.

The number of levels and specific measures incorporated into each level of DiD have evolved (NRC, 2016). More recent international references (INSAG, 1996; IAEA, 2016) identify five levels of safety for DiD. Implementation of this approach considers design, construction, and operation activities as well as accident management procedures for unexpected events. For each level of DiD, prevention and mitigation measures and the required analyses to demonstrate adequacy are highlighted in the following descriptions (IAEA, 2016).

Defense Level 1 - Prevention of abnormal operation and/or failures

The purpose of the first level ... is to prevent deviations from normal operation and the failure of items important to safety. This leads to requirements that the plant be soundly and conservatively sited, designed, constructed, maintained and operated in accordance with quality management and appropriate and proven engineering practices. To meet these objectives, careful attention is paid to the selection of appropriate design codes and materials, and to the quality control of the manufacture of components and construction of the plant, as well as to its commissioning. Design options that reduce the potential for internal hazards contribute to the prevention of accidents at this level of defense. Attention is also paid to the processes and procedures involved in design, manufacture, construction, and in-service inspection, maintenance and testing, to the ease of access for these activities, and to the way the plant is operated and to how operating experience is utilized. This process is supported by a detailed analysis that determines the requirements for operation and maintenance of the plant and the requirements for quality management for operational and maintenance practices.

Defense Level 2 - Control of abnormal operation and detection of failures

The purpose of the second level ... is to detect and control deviations from normal operational states in order to prevent anticipated operational occurrences at the plant from escalating to accident conditions. This is in recognition of the fact that postulated initiating events are likely to occur over the operating lifetime of a nuclear power plant, despite the care taken to prevent them. This second level ... necessitates the provision of specific systems and features in the design, the confirmation of their effectiveness through safety analysis, and the establishment of operating procedures to prevent such initiating events, or otherwise to minimize their consequences, and to return the plant to a safe state.

Defense Level 3 - Accident control within design basis

For the third level ..., it is assumed that, although very unlikely, the escalation of certain anticipated operational occurrences or postulated initiating events might not be controlled at a preceding level and that an accident could develop. In the design of the plant, such accidents are postulated to occur. This leads to the requirement that inherent and/or engineered safety features, safety

systems, and procedures be capable of preventing damage to the reactor core or preventing radioactive releases requiring off-site protective actions and returning the plant to a safe state.

Defense Level 4 - Control of severe plant conditions

The purpose of the fourth level ... is to mitigate the consequences of accidents that result from failure of the third level of defense-in-depth. This is achieved by preventing the progression of such accidents and mitigating the consequences of a severe accident. The safety objective in the case of a severe accident is that only protective actions that are limited in terms of lengths of time and areas of application would be necessary and that off-site contamination would be avoided or minimized. Event sequences that would lead to an early radioactive release or a large radioactive release are required to be 'practically eliminated'.

Defense Level 5 - Mitigation of radiological consequences of significant radioactive releases

The purpose of the fifth and final level ... is to mitigate the radiological consequences of radioactive releases that could potentially result from accidents. This requires the provision of adequately equipped emergency response facilities and emergency plans and emergency procedures for on-site and off-site emergency response.

A combination of systems, structures, and components (SSCs), as well as procedures and analyses, are required to achieve each DiD level. The greatest emphasis is placed on the first level of defense so plant performance is predictable during normal and abnormal conditions (NRC, 2016). As discussed in Lutz and Williamson (2021a,c), the second level of defense is achieved by the reactor protection and the instrumentation and control systems. As reported in Lutz and Williamson (2021b,d,e), ESFs and guidance for operational and beyond design basis events provide the third, fourth, and fifth levels of defense. Gauntt (2021) provides additional details regarding the analyses required for evaluating the performance of plants systems, operator actions, and measures to prevent and mitigate accident releases for each level of defense.

Regulatory framework

The regulatory framework influences the design and evaluation of ESFs. In the U.S., this regulatory framework has evolved; it includes regulatory requirements and design criteria in Title 10 of the Code of Federal Regulations (10 CFR) (U.S. Government Publishing Office, 2019) and other components, such as technical specifications, regulatory guidance, and quality assurance programs (see Bley and Malsch, 2021a,b).

After the passage of the 1954 Atomic Energy Act, the U.S. Atomic Energy Commission (AEC) confronted the task of developing regulations and licensing procedures with sufficient rigor to protect public health and safety but sufficient flexibility to allow for rapid changes in nuclear technology. Within a short time, the staff drafted rules on radiation protection, distribution and safeguarding of fissionable materials, and the qualification of reactor operators. The AEC established regulations implementing the two-step licensing process currently outlined in 10 CFR 50 (see Ray, 2021). To gain approval to proceed with construction from the AEC, applicants submitted a "Hazards Summary Report" (later renamed a "Safety Analysis Report") with available design information (which at the construction permit stage would be incomplete), a site description (including seismic, atmospheric condition, and nearby population and industrial hazard information), a detailed plan for plant operation, a schedule for chemical processing and disposal of reactor fission products, proposed methods for disposal of radioactive effluents, and a description of the reactor safety mechanisms. As described in Bley and Malsch (2021a), specific information was required about potential hazards. The applicant listed all the known potentially hazardous features and included the experimental information, calculations, and assumptions used in evaluating those hazards. The report required information on steps taken to minimize the risks and an estimate, if a failure should occur, of any release of radioactive material and the damage to be expected.

In the first decade of commercial nuclear power, the regulatory staff and their independent advisory committee, which eventually became the Advisory Committee on Reactor Safeguards (ACRS), used a case-by-case approach to evaluate construction permit applications. The technology was in its early stages and undergoing continual change; it was difficult to establish general guidelines. By early 1965, several factors, such as the expected increase in the number of new plant applications, the higher power ratings of the plants being reviewed, and recommendations from an outside review panel, led to a more formal review approach. It was hoped better documentation of AEC expectations would simplify and accelerate the licensing process. In the next several years, the AEC and later, its successor, the U.S. Nuclear Regulatory Commission (NRC), established several components of a regulatory framework that influenced the number and design of required ESFs and evaluations of their performance. This chapter describes several components within the NRC regulatory framework that significantly affect ESF design and safety analyses. Bley and Malsch (2021a,b) provide additional information about components of the NRC regulatory framework, the process used to modify this framework, and the evaluation process used to implement such modifications. Of particular relevance to this chapter, are discussions in Bley and Malsch (2021a) and Dube (2021) about the evolution of NRC regulation and guidance that limit ESF modifications or "backfits."

General design criteria (GDC)

Until 1965, there were no written criteria against which the various designs could be compared. In 1965, the AEC staff began drafting what would eventually become the General Design Criteria (GDC) initially published in 1971 as Appendix A of 10 CFR 50

(U.S. Government Publishing Office, 2019). The GDCs state broad requirements but leave the means for achieving them to the applicant. In licensing submittals, applicants must present their plans and sufficient supporting technical data to demonstrate their design would meet each of the GDC (or submit requests for exemptions with supporting information).

The GDC have been and continue to be updated as insights are gained from operating experience and analyses. The current version of the GDC address 64 broad issues grouped into six major categories:

- overall requirements
- protection by multiple fission product barriers
- protection and reactivity control systems
- fluid systems
- reactor containment
- fuel and reactivity control

The GDC are an important part of the NRC's regulatory framework. For Light Water Reactors (LWRs), they provide minimum requirements related to design, fabrication, construction, testing, and performance requirements for SSCs important to safety. The GDC can be adapted to establish principal design criteria (PDC) for non-LWRs (USNRC, 2018). The GDC serve as the fundamental criteria for the NRC staff when reviewing the ability of SSCs to perform their intended safety functions during design basis events. All production and utilization facilities licensed under 10 CFR 50 or 10 CFR 52, including both LWRs and non-LWRs, are required to describe their PDC.

Technical specifications

The GDC itemize broad objectives that applicants should address. They did not, however, spell out the nature and extent of the technical data the AEC expected applicants to supply. By listing safety information the AEC required from applicants, the Technical Specifications (or "tech specs") sought to accelerate and rationalize the licensing process while at the same time improving safety. Today, Technical Specifications are part of the facility design bases; hence, they are part of the NRC license authorizing the facility's operation. Technical Specifications establish requirements for items such as safety limits, limiting safety system settings, limiting control settings, limiting conditions for operation, SSC surveillance, design features, and administrative controls. Technical Specifications include: "nuclear limits" for amount of energy extracted from the fuel, value and sign of reactivity feedbacks, reactivity worth per control rod, and core axial and radial power distribution; "reactivity control limits" for shutdown margin, control rod withdrawal or insertion speeds, and emergency shutdown provisions; "thermal and hydraulic limits" for peak fuel and clad temperatures, coolant flow velocities, and thermal hydraulic stability; and "mechanical limits" for maximum stresses, fatigue, and seismic shock loads.

Guidance

The GDC do not provide quantitative bases for establishing the adequacy of any particular design. The development of more detailed regulatory guidance began in the late 1960s when the regulatory staff started generating internal documents outlining acceptable approaches for specific designs. In 1970, the AEC began publishing regulatory guides. The first published regulatory guide dealt with the concern that a loss of containment integrity should not compromise the ability of the emergency core cooling system (ECCS) to ensure its critical safety functions. This regulatory guide required sources of ECCS water be at sufficiently high pressure (provide sufficient net positive suction head) to avoid pump cavitation. Within a short time, the regulatory staff prepared regulatory guides on a wide variety of issues, ranging from thermal shock to assumptions used for estimating the radiological consequences of a loss-of-coolant accident (LOCA). These regulatory guides supplemented existing safety requirements on siting, radiation protection, and other matters. In addition, the staff issued an initial version of the Standard Review Plan (see NRC, 2019), which provides guidance for reviewing the content of regulatory applications and license amendments for LWRs. Although not regulatory requirements, these guidance documents alerted applicants of topics that had to be considered in their submittals. Applicants, as well as plant owners/operators found it easier to follow a design or analysis approach that had been prejudged by the regulator as acceptable than to defend an alternative approach. As appropriate, the NRC staff worked with professional societies to develop standards that could be endorsed by the staff in regulatory guides. As an example, consider guidance related to **Quality Assurance**.

Quality Assurance

The need to assure quality in the manufacture of SSCs and in plant construction is emphasized in the first level of **Defense-in-Depth (DiD)**; the need for this assurance took on greater importance when plant size increased. Within 10 CFR 50 can be found several Quality Assurance (QA) program requirements:

- Criterion 1: "Quality Standards and Records," in Appendix A to 10 CFR 50 requires a QA program be established and implemented.

- Appendix B “Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants,” outlines guidance for this QA program.
- 10 CFR 50.34(a)(7) requires a description of the QA program to be applied in the design, fabrication, construction, and testing of the facility SSCs, and a discussion of how the applicable requirements of 10 CFR 50 Appendix B will be satisfied.

Similar QA program requirements were later adopted for 10 CFR 52 (see [Ray, 2021](#)), which references applicable sections of Appendix B to 10 CFR 50. Similar to the GDC, the QA criteria told applicants what to do but not how to do it. Guidance the NRC finds acceptable for a QA program, however, can be found in several regulatory guides (e.g., Regulatory Guides 1.33 ([NRC, 2013](#)) and 1.28 ([NRC, 2017](#)) and the Standard Review Plan ([NRC, 2019](#))). The regulatory staff works with professional societies to establish equipment, fabrication, and inspection codes. The staff consults with organizations, such as the ANS, the ANSI, the American Society of Mechanical Engineers (ASME), and the Institute of Electrical and Electronics Engineers (IEEE), to prepare guidelines on the reliability and testability of nuclear pressure vessels, pipes, valves, pumps, reactor protection systems, and in-service inspection of safety equipment. Special criteria were developed for fluid boundaries, for radiation containments, and penetrations to assure required safety functions are maintained. Where appropriate, testing and surveillance requirements are provided.

Safety evaluation importance example

As emphasized in [Gauntt \(2021\)](#), safety evaluations play an important role in the development and deployment of commercial nuclear power plants. Safety evaluations are essential in demonstrating **Critical Safety Functions** are maintained and in providing assurance various **Defense-in-Depth (DiD)** measures exist. As knowledge has been gained from operating experience and unexpected events, regulatory requirements and guidance for such evaluations evolved. These changes affected the design of plant SSCs. However, there are also examples in which analyses completed with updated models, based on additional experimental data, were used to revise the regulations. One such example related to ECCS regulatory requirements is highlighted here.

Background

Evaluation of the suitability of a site is an important aspect of licensing. The effectiveness and reliability of safety features, in conjunction with the distance to population centers, are important in determining the adequacy of proposed sites. Credit for ESFs was sought to allow siting of reactors at locations where, without such features, protection of the public would not be adequate (e.g., 10 CFR 100 criteria would be exceeded). Applicants attempted to get maximum credit for ESF reductions in containment pressure and radionuclide concentrations during a postulated large break LOCA (LB LOCA). The ESFs for which credit was routinely given include the leak-tight containment, the pressure suppression pool in Boiling Water Reactors (BWRs), containment building sprays in Pressurized Water Reactors (PWRs), containment heat removal systems, and containment air-cleaning systems (see [Lutz and Williamson \(2021b\)](#) for more details about ESFs found in PWRs and BWRs).

As power levels of proposed plants increased significantly, however, ACRS began to worry that a core melt could lead to a breach of containment [Okrent, \(1981\)](#). This became more of a concern not only because of the greater decay heat associated with higher power level reactors but also because the containment building volume (which partially controlled increases in temperature and pressure) was not proportionally increased with reactor power level. Hence, there was the potential the safety margin in newer plants was decreased.

Although plants are designed to withstand a spectrum of postulated accidents, the design-basis LB LOCA, whose consequences were not to be exceeded by any other credible accident, became the focus of siting evaluations. In November 1964, the ACRS discussed various safety features and their evaluations of them, emphasizing the need for additional confidence in ECCS performance as units with higher power levels were proposed for metropolitan sites (i.e., these safety features had to compensate for the lack of protection associated with distance from a population center). As discussed in [Lutz and Williamson \(2021b\)](#), one of the primary functions of the ECCS is to provide cooling (by water injection and alternate cooling systems) following a LB LOCA. Although deemed essential for prevention of core melting, the lack of data to provide confidence in ECCS performance led ACRS to recommend ECCS failure be assumed in estimating radionuclide releases postulated for siting.

New test data

In response to concerns about ECCS performance, the AEC initiated a testing and analyses program to be primarily conducted at what is now known as the Idaho National Laboratory (INL). This test program included several smaller scale preliminary tests at the Semiscale facility followed by larger scale, integral tests at the Loss-of-Fluid Tests (LOFT) facility.

In the summer of 1970, small-scale ECCS test results and analyses prompted concern among researchers ([Walker, 1992](#)). Several small-scale experiments conducted in Idaho and other locations indicated that in the event of a LB LOCA, core temperatures could rise higher than previously believed and the coolant from the ECCS might not reflood the core as rapidly as expected. In November and December of 1970, results from the initial Semiscale tests caused more concern. These tests were performed using a ~23 cm high core (compared to reactors with ~366 cm high cores) in a vessel with one set of inlet and outlet pipes. Their purpose was to study the effectiveness of ECCS under accident conditions. The experiments were run by electrically heating the simulated core,

allowing cooling water to escape, and then injecting emergency cooling water. Rather than cooling the core, the high steam pressures within the vessel resulted in about 90% of the injected water directly exiting through the outlet pipe. In January 1971, Idaho researchers reported: “Preliminary analysis of the results of these tests indicates little or no cooling by the emergency coolant” (INC, 1971).

The size, scale, and design of the Semiscale test, in particular the channels directing the flow of coolant in the test model, differed from those of an actual reactor. Unlike commercial plants, which had two to four coolant loops, the test equipment used a single loop. This increased the possibility of emergency coolant bypassing the core and flowing out the break in the single loop rather than reaching the core through other paths. Nevertheless, the unanticipated Semiscale test results raised safety concerns. To initially address these concerns, the AEC published “interim acceptance criteria” in 1971 (USNRC, 2002) until further research could be completed. These criteria required additional maintenance and monitoring in addition to changes in the ECCS designs of some operating reactors. These interim ECCS criteria were similar to what would later be promulgated in 10 CFR 50.46 (see **Regulatory framework modifications**).

In 1973, a second series of experiments was completed. These later tests were called 1½ Semiscale because a loop simulating the unbroken loops of a reactor was added to the ½ (broken) loop. This time, water was injected through the unbroken loop, as would occur during ECCS injection within actual power reactors with two, three, or four loops. As predicted by computer models, the simulated core was successfully cooled in all 1½ Semiscale tests with steam escaping through the broken loop.

Regulatory framework modifications

In 1974, the NRC set up safety requirements based on DiD in 10 CFR 50.46 and provided guidance in 10 CFR 50 Appendix K for models and simulations to ensure conservatism in predictions. These methods resulted in both conservative safety margins as well as economic and operational penalties. In the late 1970s and early 1980s, a large number of experiential programs provided additional data for developing best estimate models. Eventually, these models were used to justify additional changes to ECCS regulatory requirements.

First promulgated in 1974, ECCS requirements include 10 CFR 50.46(b) acceptance criteria:

- (1) *Peak cladding temperature (PCT)*. The calculated maximum fuel element cladding temperature shall not exceed 2200 °F (1200 °C).
- (2) *Maximum cladding oxidation*. The calculated total oxidation of the cladding shall nowhere exceed 0.17 times the total cladding thickness before oxidation.
- (3) *Maximum hydrogen generation*. The calculated total amount of hydrogen generated from the chemical reaction of the cladding with water or steam shall not exceed 0.01 times the hypothetical amount that would be generated if all the metal in the cladding surrounding the fuel were to react.
- (4) *Coolable geometry*. Calculated changes in core geometry shall be such that the core remains amenable to cooling.
- (5) *Long-term cooling*. After any calculated successful initial operation of the ECCS, the calculated core temperature shall be maintained at an acceptably low value and decay heat shall be removed for the extended period required by the long-lived radioactivity remaining in the core.

The AEC also provided guidelines, which are now found in Appendix K of 10 CFR 50, for ECCS evaluation models for satisfying 10 CFR 50.46(b) acceptance criteria. These guidelines were created to ensure the predicted safety parameters were conservative. Furthermore, if simulations demonstrated acceptance criteria were met, the guidelines provided assurance there would be large margins to actual failure limits. The AEC and its successor, the NRC, reviewed ECCS designs of every operating plant. When necessary, ECCS retrofits and upgrades were required or the operating power level was reduced to assure compliance with the criteria. Indian Point 1 was shut down in October 1974 because of an inadequate ECCS. All new plants and plants under construction were required to meet the criteria. Although the Appendix K methods were very conservative, these methods also led to predictions of non-physical behavior during the transition from depressurization to reflood phases occurring during a LB LOCA (Hochreiter et al., 1992; Rohatgi and Kaizer, 2020). There was concern evaluations were predicting an entirely different sequence of phenomena than what would be expected during an actual event.

To understand how the use of an Appendix K approach affects calculation results, it is helpful to consider Fig. 2 (Rohatgi and Kaizer, 2020). There is a safety limit (such as PCT) above which the fuel cladding will become damaged. A regulatory requirement (or acceptance criterion) is placed below this safety limit; if this regulatory requirement is met, damage is precluded. For a specific safety limit, there is a predicted value for what would occur during an accident (e.g., LB LOCA). However, it is recognized estimates for this value are uncertain (due to uncertainty in analysis models and their input). The Appendix K approach is to quantify these uncertainties using engineering judgment and to choose bounding values for model input parameters. Thus, the Appendix K approach should bias analysis to make predictions conservative with respect to the regulatory requirement (i.e., leading to the “Conservative Margin to Acceptance Criterion” shown in Fig. 2).

There can be complications with an Appendix K approach. First, conservative biases are dependent on the selected safety limit. If the figure of merit changes (e.g., from PCT to peak containment pressure), initially conservative assumptions may become non-conservative. Second, it may be difficult to discern the conservative direction for some model input parameters. While some figures of merit may linearly increase or decrease with certain parameters (e.g., decay heat), reactor analysis tends to be non-linear and the “worst case” for many parameters may not be easily understood. Third, results from a conservative analysis may be

Fig. 2 Comparison of uncertainties and safety margin obtained with Appendix K and Best Estimate Plus Uncertainty (BEPU) approaches. From Rhatgi and Kaizer (2020) Historical Perspectives of BEPU research in US. *Nuclear Engineering and Design*, 358, March 2020.

non-physical, thus limiting any obtained insights. Hence, results showing less margin to regulatory limits may lead to unnecessary penalties on reactor operation.

After results were obtained from the Semiscale tests, several independent assessments of ECCS criteria were completed. For example, the NRC sponsored additional experiments to investigate individual phenomena and system performance and funded development of advanced computer codes for improved simulations of LOCAs. These experimental and computational efforts provided the technical basis for a revised rule for ECCS performance. The rule was approved by the NRC in September 1988. The revised rule retains the acceptance criteria based on PCT, cladding oxidation, and hydrogen generation; however, it allows the use of best-estimate computer codes for evaluating these parameters. If a Best Estimate plus Uncertainty (BEPU) analysis is performed, the revised rule requires calculation uncertainties be quantified and included when comparing predicted results with the acceptance limits provided in 10 CFR 50.46(b). As shown in Fig. 2, results from a Best Estimate Plus Uncertainty (BEPU) analysis provide a larger, more realistic estimate of plant safety margins (the “BEPU Margin to Acceptance Criterion”), leading to additional margin compared to results obtained with the Appendix K approach (the “Benefit of BEPU Analysis”). This additional margin can be used to reduce unnecessary financial penalties, such as limits on fuel discharge burnup, and allow more flexible plant operation, such as relaxations in equipment technical specification requirements.

Summary

Nuclear power plant safety is assured by maintaining three critical safety functions. This chapter provides an overview of the DiD approach used to ensure these safety functions are maintained. This approach, which is enforced by a regulatory framework, emphasizes measures implemented in reactor design and evaluation activities. This chapter also includes an example illustrating the use of evaluations to justify changes in the regulatory framework. In this example, regulations were modified to allow more realistic calculations for demonstrating compliance with core cooling requirements.

Glossary

Analog A continuous signal that represents a time varying quantity. An example is the signal from an instrument sensor which indicates the parameter value is continuously transmitted as it varies with time.

Anticipated Transient Without Scram (ATWS) The failure of the control rods to fully insert in response to a condition in which automatic reactor scram is expected to occur.
